Introductory Review

Population genomics: patterns of genetic variation within populations

Greg Gibson
North Carolina State University, Raleigh, NC, USA

1. Polymorphism

Polymorphism at the nucleotide level ranges over at least an order of magnitude within species, and average polymorphism ranges over two orders of magnitude between species. *Homo sapiens* is among the least polymorphic of all species, with a heterozygous single nucleotide polymorphism (SNP) generally occurring once every 500 to 1000 bp (International SNP Map Working Group, 2001). By contrast, marine invertebrates such as the sea squirt and echinoderms have an astonishing level of sequence diversity with a SNP every 5 to 10 bp (Dehal *et al*., 2002). Diversity is a function of organism-level factors such as population size, generation time, and breeding structure (Aquadro *et al*., 2001), but variation within and among chromosomes signifies that recombination and mutation rates are also critical (Begun and Aquadro, 1992; Charlesworth *et al*., 1995). In most species, centromeric and telomeric regions are less recombinogenic, hence have smaller effective population sizes, and tend to be less polymorphic (Nachman, 2002). Even within a locus, polymorphism can vary over an order of magnitude, according primarily to functional constraint: synonymous substitution rates tend to be uniform, whereas replacements can be excluded from highly conserved domains. Noncoding gene sequences are typically more polymorphic than exons and less polymorphic than intergenic DNA, but core regulatory sequences up to several hundred basepairs in length may often be the most conserved of all sequences (Wray *et al*., 2003).

Significant disparity between two measures of polymorphism, namely, the number of segregating sites and the average heterozygosity, provides evidence for departure from "neutrality" (Hudson *et al*., 1987; Kreitman, 2000). However, neutrality comes in many flavors, and demographic processes are just as likely to affect the difference between these two measures as is selection (Nielsen, 2001). Heterozygosity is a function of allele frequency as well as density, so unexpectedly high or low numbers of heterozygotes relative to the number of SNPs in a population can arise as a result of several processes that may be superimposed on random drift. Thus, rapid population expansion or strong purifying selection both reduce

heterozygosity, whereas admixture or balancing selection will increase heterozygosity. Tests such as Tajima's D (Tajima, 1989) have remained useful descriptors of diversity, but have been joined by a new series of tests that are more firmly rooted in coalescent theory (Wall and Hudson, 2001). Rather than strictly interpreting test scores relative to theoretical expectations, comparison of the distribution of test scores across tens or hundreds of loci among species emphasizes that diversity is affected by a complex interplay of factors and that it is the location of a gene at either extreme of the continuum that marks it as a candidate target of selection, rather than a p-value per se (Hey, 1999; Bustamante *et al*., 2002).

A trend toward empirical evaluation of significance by permutation in light of genomic data is also seen in relation to population structure. Standard F-statistics introduced by Sewall Wright based on differences in genotype frequencies among populations (Weir and Hill, 2002) have been extended into an analysis of molecular variance (AMOVA) framework, one popular implementation of which is the Arlequin software (Schneider *et al*., 2000). Estimates of SNP, indel, haplotype, or microsatellite allele frequency differences are sensitive to sample size, so samples of at least 100 individuals per population are recommended. Using genomic data, the multiple comparison issue also arises: in a set of 500 sites, a single site with a testwise p-value of 0.0001 is not unexpected, but in a large sample this may correspond to an allele frequency difference of just 10%. Consequently, population structure is best estimated from multilocus data. For example, Pritchard *et al*. (2000) have introduced Bayesian statistics to assign individuals to likely subpopulations with numerous applications in evolutionary, conservation, quantitative, and human genetics. It is well known that over 90% of all human polymorphism is common to all populations, but the ability to genotype hundreds of loci has led to the recognition that given sufficient data there is a detectable signature of demographic history even in our species (Rosenberg *et al*., 2002). Similarly, long-held assumptions of panmixia in *Drosophila melanogaster* are being challenged by deeper sampling (Glinka *et al*., 2003), as are commonly held notions about the genetic uniformity of crops such as maize (Matsuoka *et al*., 2002), and in fact the power to discriminate population structure in most species will have a profound impact on quantitative biology. An important implication of the ability to detect population structure is inference of departure from neutrality, by comparison of the observed F-statistics with those obtained from a collection of assumed neutral markers (Lewontin and Krakauer, 1973; Rockman *et al*., 2003).

The advent of new sequencing and genotyping technologies will only accelerate the data-driven nature of evolutionary genetic research (*see* Article 7, **Single molecule array-based sequencing**, Volume 3). ABI 3730 automated DNA sequencing machines routinely generate traces with over 1 kb of high-quality sequence and have a throughput capacity exceeding 1 Mb per day. Single-molecule sequencing methods are expected to make the sequencing of complete eukaryotic genomes for $1000 each a reality, possibly in the next decade (Meldrum, 2000), while massively parallel resequencing by hybridization to wafers of tiled oligonucleotides has already been used to characterize polymorphism between primate species (Frazer *et al*., 2003). Such studies have identified hundreds of loci that are candidates for the adaptive evolution in the recent human lineage, some of which are likely to contribute to the etiology of common disease (Tishkoff and Verrilli, 2003;

Clark *et al*., 2003). Molecular evolutionary studies of single genes in samples of 30 individuals have been typical but will soon be dwarfed by genome-scale sampling, and increasingly, attention will be placed on the efficient sampling design and formulation of hypotheses that utilize patterns of variation across the genome to interpret unusual patterns of variation at focal loci. Describing the variance of standard population-genetic parameters at a genome-wide scale is unprecedented territory, and developing approaches to quantify this variation across these expansive contiguous regions is the challenge for the near future. This type of data will also allow reexamination of some of the most basic assumptions underlying many population-genetic approaches, such as the infinite sites and island migration models.

2. Recombination and linkage disequilibrium

Recombination and mutation are the two biochemical processes that influence the distribution of molecular variation. Recombination can be directly measured by monitoring the coinheritance of markers transmitted from parent to offspring, but with the exception of technically demanding single sperm typing (Jeffreys *et al*., 2000); the resolution of this method is of the order of just centimorgans or hundreds of kilobases. Since an important consequence of recombination is its effect on linkage disequilibrium over scales from tens of bases to tens of kilobases, indirect methods for measuring recombination have been introduced based on population-genetic measurement of the cosegregation of markers (Hudson and Kaplan, 1985; Stumpf and McVean, 2003). Linkage disequilibrium (LD) is the nonrandom assortment of genetic markers: given two alleles each at a frequency of 20%, just 4% of individual chromosomes should have both alleles if assortment is random, but physically adjacent markers will often cosegregate more often. In this case, the maximum possible LD would have 20% of the chromosomes with both less common alleles, and 80% with both common alleles. Two commonly used statistics measure this departure from randomness, D' and r^2, only the latter of which explicitly takes allele frequencies into account (Hill and Robertson, 1966; Weir, 1996). A further technical challenge in the measurement of LD is establishing the linkage phase of double heterozygotes, which can be addressed directly by studying trios of parents and their offspring (which is however impractical for many species) or computationally with EM likelihood algorithms (Fallin and Schork, 2000; Stephens *et al*., 2001).

Quantitative geneticists have long been interested in LD because detection of association between markers and phenotypes is dependent on LD between anonymous markers and the causative disease or quantitative trait nucleotide(s) (Zondervan and Cardon, 2004). This idea has given rise to the human HapMap project, which is an effort to describe the complete pattern of haplotypes in the human genome (International HapMap Consortium, 2003). Haplotypes are sets of multilocus alleles, and because of LD they tend to be less common than chance would predict: there are 32 possible ways that five biallelic alleles can combine, but typically just a handful of these will be at any appreciable frequency in a population. Standard population-genetic theory predicts that LD should decay monotonically with distance, but at least in the human genome it now appears that there are often

fairly discrete boundaries that define haplotype blocks that range in length from 10 to 100 kb or more (Gabriel *et al*., 2002; *see also* Article 12, **Haplotype mapping**, Volume 3 and Article 74, **Finding and using haplotype blocks in candidate gene association studies**, Volume 4). Consequently, while there are in excess of 5 million SNPs in the human genome, there may be as few as 50 000 common haplotype blocks, and consequently it is argued that a similar number of markers will be sufficient to perform genome scans for association with disease (Risch and Merikangas, 1996). According to the common disease–common variant hypothesis, the polymorphisms that contribute to many complex human diseases are likely to have arisen early in human history, but sufficiently recently that they remain embedded in observable common haplotypes. Similarly, selected phenotypes or polymorphic traits of interest to evolutionary biologists and ecologists may be due to nucleotide variants that can be identified by LD mapping.

There is considerable debate over the reasons for the detection of haplotype blocks, with explanations ranging from sampling variance to unequal recombination rates and/or gene conversion hotspots within loci (Wall and Pritchard, 2003; Stumpf and Goldstein, 2003), and study of the population structure of haplotypes are in their infancy. With respect to evolutionary and agricultural genetics, measurement of haplotype structure is increasingly important. Domesticated crops and livestock are likely to have strong haplotype structure as a result of their breeding history (Flint-Garcia *et al*., 2003), whereas outbred and highly polymorphic species such as *Drosophila melanogaster* are almost devoid of haplotypes (*see* Article 10, **Linking DNA to production: the mapping of quantitative trait loci in livestock**, Volume 3). More recent is the advent of population genetics in nonmodel systems that are important with respect to epidemiology, particularly in humans, such as HIV and *Plasmodium* (malaria). The frequency of outcrossing or mixing among these species may contribute to these organisms' ability to evade host immunity (Awadalla, 2003). The ability to dissect quantitative traits to the nucleotide level in any species is ultimately dependent on the thorough characterization of haplotype diversity.

3. Mutation, gene content, and the transcriptome

Population genomics also encompasses several novel aspects of variation that were beyond the technical reach of classical population genetics. For example, direct measurement of mutation rates is now possible, and will complement a large body of literature on the genetic consequences of mutation accumulation (Keightley and Lynch, 2003). For many species, it has been estimated that new genetic variance for fitness or morphological traits is generated at a rate within an order of magnitude of 0.1% of the environmental variance per generation (Clayton and Robertson, 1955; Houle *et al*., 1996). Similarly, genetic evidence suggests that a typical per locus spontaneous mutation rate is approximately 10^{-6} per generation, from which nucleotides are inferred to substitute in each meiosis at a rate close to 10^{-9}. Microsatellites evolve at a much accelerated rate, but with a high variance, as directly measured by comparison of parent and offspring genotypes in several studies (Ellegren, 2000). Insertion–deletion (indel) polymorphism is prevalent,

particularly in studies of regulatory regions of genes, but has been relatively neglected by theoreticians because of the absence of good molecular data on the tempo and mode of indel generation (Li, 1997). Genomic sequence data from invertebrates such as the nematode *Caenorhabditis elegans* that can be propagated essentially clonally (with a population size of 1) will provide measurements of mutation rates independent of the filter of natural selection (Vassilieva *et al*., 2000), offering a crucial comparison with standing variation in natural populations.

Gene order and content is unlikely to be highly polymorphic within populations of multicellular eukaryotes, but has emerged as a challenging feature of microbial genetics. A mixture of processes including conjugation, horizontal transfer from other species, plasmid shuffling, and spontaneous deletion or duplication, result in differences among congeneric bacteria affecting 10% or more of the genome (Ochman and Jones, 2000; Daubin *et al*., 2003; *see also* Article 66, **Methods for detecting horizontal transfer of genes**, Volume 4). Whole-genome sequence comparisons have revealed the existence of pathogenicity and virulence islands of genes that distinguish isolates of *Bacillus*, *Escherichia*, and several other bacterial species (Whittam and Bumbaugh, 2002; Hacker and Kaper, 2000), but more generally it has been suggested that each species is defined by a core set of definitive genes that are accompanied by hundreds of variable genes whose presence defines the metabolic capacity of each isolate (Lan and Reeves, 2001). Our conception of microbial diversity is under equally profound challenge through the advent of whole-flora shotgun sequencing, an approach designed to characterize new species that cannot be cultured in vitro (De Long, 2002; Venter *et al*., 2004). As many as 90% of the microbial species in water, soil, and body cavities remain to be described, and genomic arrays will also be developed for use in monitoring diversity in microbial ecosystems.

Finally, the structure of transcriptional variation is emerging as a new field of enquiry (*see* Article 90, **Microarrays: an overview**, Volume 4). Almost no attention has been given to the prevalence of variation for alternative splicing, despite the fact that mutational studies indicate that a considerable fraction of sites affect splicing efficiency in a quantitative manner (Cartegni *et al*., 2002). Transcript abundance itself is also variable among individuals, as a result of both environmental and genetic factors (Yan and Zhou, 2004). Estimates from half a dozen species indicate that at least 10% of the transcriptome differs in abundance between any two individuals, but almost nothing is known of the tissue and temporal specificity of differential transcription (Cheung and Spielman, 2002; Gibson, 2002). Descriptors of the frequencies of qualitatively distinct levels of transcript abundance as well as the cosegregation of these "transcriptional alleles" within and among populations, as well as their heritability, will be a fundamental component of future efforts to describe the genetic architecture of complex traits.

Modeling human genetic history

Lounès Chikhi

Université Paul Sabatier, Toulouse, France

University of Reading, Reading, UK

1. Introduction

The genetic patterns observed today in the human species are the result of a complex history including population expansions and collapses, migration, colonization, extinction, and admixture events. These events have taken place in different locations and times, sometimes involving populations that have been separated for centuries or millennia. Given that anatomically modern humans probably appeared some 100–200 thousand years ago (KYA) in Africa, it would certainly be ingenuous to think that the details of that history will be fully uncovered using genetic data. However, it would probably be equally misguided to refuse the use of simple models on those grounds.

Indeed, genetic data have revolutionized the way we look at our species in many ways. They have shown that the split between human, chimpanzees, and gorillas is rather recent, between 5 and 8 million years old (Nichols, 2001), instead of twice as much as was originally believed on the basis of morphological and fossil data. They have shown that the amount of genetic variation within single populations represents a major proportion (~85–90%) of the diversity present in the human species as a whole, indicating that despite the sometimes large phenotypic differences between some human groups, genetic diversity is not very strongly partitioned. They have contributed to the debate over recent migration patterns, the emergence of our species, or its relationships with Neanderthals. In particular, genetic data have been the major driving force in favor of a recent origin of our species, notably thanks to work done using mitochondrial DNA data in the late 1980s and early 1990s (Cann *et al*., 1987; *see also* Article 5, **Studies of human genetic history using mtDNA variation**, Volume 1).

The modeling work performed in this period showed a significant genetic signal for a demographic bottleneck followed by a demographic expansion, the dating of which was recent (i.e., less than 200 KYA, Slatkin and Hudson, 1991; Rogers and Harpending, 1992), a result found across genetic markers, including independent microsatellite loci (Goldstein *et al*., 1995; Reich and Goldstein, 1998). These

inferences appeared to reject the so-called multiregional (MR) model and to favor a model of recent expansion out of Africa (RAO for recent African origin or OOA for out of Africa), which had the advantage that it correlated with the first appearance of anatomically modern humans. The MR model, which should probably be seen as a family of models (Goldstein and Chikhi, 2002), assumes an ancient origin (more than 1 million years ago, MYA) of human populations. It also posits some regional continuity between present-day populations in the different continents and the early migrations out of Africa of archaic hominids. The RAO model also had the advantage of explaining the limited diversity observed in humans and the lack of strong differentiation between present-day populations, both being higher in chimpanzees despite their much more limited geographical range and census sizes. Thus, in the mid-1990s, the picture could not have been clearer and it seemed to many that only the details needed to be worked out. Fifteen years later, one has to admit that it could not be further from the truth. The increasing use of independent genetic markers, including coding genes, and the rather different modeling assumptions used by various authors have led to a confusing literature from which opposite conclusions have been drawn (Excoffier, 2002). Even assuming that there is a general genetic signature for a recent demographic expansion, it is not necessarily straightforward to conclude in favor of the RAO, as noted by Wall and Przeworsky (2000) and others. The link between genetic results and archaeological, linguistic, or anthropological debates and controversies is not as simple as some would like to believe.

The aim of this article is to describe some of the simple models that have been used to decipher broad trends in that complex history. Principles underlying demographic inference based on genetic data are presented. In particular, we show how summary statistics are differentially influenced by demographic events such as expansions and contractions. We also present some results from the coalescent theory, which focuses on the properties of gene trees and plays a major role in population genetics modeling. We then discuss some recent methodological developments including Bayesian and the so-called approximate Bayesian computational methods (Beaumont *et al*., 2002; Marjoram *et al*., 2003; Beaumont and Rannala, 2004) and try to address a number of the issues that are the focus of ongoing research, including the use of ancient DNA data or the use of patterns of linkage disequilibrium (LD) in the genome (Stumpf and Goldstein, 2003; *see also* Article 1, **Population genomics: patterns of genetic variation within populations**, Volume 1).

Given the ever-increasing importance attached to genetic data, by nongeneticists and geneticists alike, it should be stated at the outset that the amount of information that can be extracted from genetic data to infer past events is often limited and consequently requires a priori assumptions. There are two fundamental problems: (1) Genetic data only contain information on the relative rates of different processes in the history of the population. This means that it is impossible to make statements about the times of events or population sizes without some external reference, such as mutation rates, or the dating of splits of populations from archaeological evidence. (2) As discussed below, population genetics theory suggests that the vast majority of genes in humans that lived in the past have left no descendent copies

today owing to genetic drift, and consequently there will be no simple relation between the history told by archaeological remains and that told by the genes.

2. Principles of demographic inference from genetic data: information extracted from summary statistics and gene tree shapes

In this section, we describe how the demographic history influences genetic patterns by first describing its effects on some summary statistics and then on the shape of gene trees. This allows us to review some results of the coalescent theory and then address some issues regarding parameter inference.

2.1. Summary statistics are differentially affected by demographic events

The detection and quantification of past demographic events relies on the fact that specific events leave a genetic *signature* in present-day populations. Meaningful inference will therefore be possible only if these signatures are sensitive to specific demographic scenarios, and unlikely to be affected by others. A richly explored area of analysis has been the study of the effect of changes in population size on different summary statistics. For instance, a stationary (or stable) population can be characterized by the scaled mutation rate $\theta = 4N_e\mu$ (for diploids) where N_e is the effective population size and μ the locus mutation rate. There are different estimators of θ, on the assumption of a stationary population, which are based on different summary statistics calculated from the data (see below). If the population is growing or contracting, the expected values of these estimators diverge from each other, and this can be used to detect population growth or decline.

A commonly used statistic that summarizes genetic diversity is the heterozygosity expected under Hardy–Weinberg conditions $H_e = 1 - \sum(n_i/n)^2$ where n_i is the observed allelic count of the ith allele. Under an infinite allele model, Kimura and Crow (1964) showed that in a stable population $E[H_e] = \theta/(\theta + 1)$, which can be used to obtain an estimate of θ. Another way to estimate θ comes from the work of Ewens (1972) who studied the sampling properties of neutral alleles in a demographically stable population for the infinite allele model. Ewens showed that at mutation-drift equilibrium, the expected number of distinct alleles, n_A, in a sample of size n is a function of n and θ only:

$$\begin{aligned} n_A &= \frac{\theta}{\theta} + \frac{\theta}{\theta+1} + \frac{\theta}{\theta+2} + \cdots + \frac{\theta}{\theta+2n-1} \\ &= \sum \frac{\theta}{\theta+i} \quad (\text{for } i = 0 \ldots 2n-1) \end{aligned} \tag{1}$$

Under these null-model conditions, he also characterized the expected allelic frequency distribution, showing that it is a function of θ, n, and n_A. This distribution obtained from what is now known as Ewens' sampling formula, provided the

means for testing departures from the null-model (Watterson, 1978). Indeed, H_e values can be computed using n_i values or using Ewens' sampling formula (i.e., ignoring allelic counts). In fact, Watterson originally used the homozygosity that is equal to $1 - H_e$, but H_e is more commonly used now. Significant differences between the two H_e values can then be interpreted in terms of departures from any of the neutrality, size constancy, or mutation model assumptions. When large populations go through a bottleneck, rare alleles are lost first, thereby reducing n_A significantly. Since H_e computed as $1 - \sum(n_i/n)^2$ is little influenced by rare alleles (their frequency is squared), high H_e values will be maintained for relatively longer periods. Thus, observed H_e values will be significantly higher than those expected conditional on n_A and equilibrium conditions. Conversely, expanding populations will tend to accumulate new (and hence rare) alleles, and significantly lower values of H_e will be observed, so long as a new equilibrium is not reached. Simple summary statistics such as n_A and H_e thus contain information on ancient demographic events. So long as simple demographic histories and a simple mutation model can be assumed, a straightforward interpretation is possible.

Since the early work of Ewens and Watterson, the approach has been extended to apply to different mutation models and hence to different genetic markers (Tajima, 1989a,b; Fu and Li, 1993) and different summaries of the data. For instance, Marth *et al*. (2004) studied the properties of the full allele frequency spectrum under different demographic scenarios, and found computationally quick ways to estimate these frequency spectrums. Similar approaches based on other aspects of the allelic distribution have been used. For microsatellites, whose alleles are defined by the size of an amplified DNA fragment consisting of small repeated units, Reich and Goldstein (1998) suggested to use an index of peakedness mathematically related to the distribution's kurtosis. The rationale was that stable populations tended to have ragged allelic distributions, whereas expanding populations had smoother, often unimodal distributions. With a similar rationale, Garza and Williamson (2001) showed that bottlenecked populations tended to have gappy allelic frequency distributions, whereas the allelic range was little affected.

For DNA sequence data, H_e and n_A are not the most appropriate measures of diversity because they do not account for the amount of mutations between alleles. The mean number of nucleotide differences between sequences, π, and S, the number of segregating sites (i.e., single-nucleotide polymorphisms or SNPs) are more suitable. Both statistics have been shown to provide two estimators, θ_S and θ_π, of the scaled mutation parameter, θ, at mutation-drift equilibrium and to be differentially affected by demographic events and selection (Tajima, 1989a,b). Tajima (1989a) hence suggested the use of $D = (\theta_\pi - \theta_S)/[\mathrm{Var}(\theta_\pi - \theta_S)]^{1/2}$, as a measure of departure from equilibrium conditions. Demographic bottlenecks and balancing selection tend to reduce S without affecting π very much and hence to produce positive D values, whereas population expansions and positive selection (selective sweeps) tend to produce negative values. As we shall see below, the situation is actually more complicated (*see* Article 4, **Studies of human genetic history using the Y chromosome**, Volume 1 and Article 5, **Studies of human genetic history using mtDNA variation**, Volume 1).

2.2. The shape of gene trees

Where an ordinal genetic distance can be defined between alleles, such as DNA sequences, and microsatellite alleles, it is possible to summarize or represent genetic diversity, not by a number, like π or H_e, but by a distribution of allelic pairwise distances. These pairwise difference or mismatch distributions have been extensively used and are also sensitive to demographic events (Slatkin and Hudson, 1991; Rogers and Harpending, 1992). Since, the interpretation of such distributions is easier from a gene tree perspective, we first review some results of the coalescent theory, which is the backbone of population genetic modeling. The coalescent theory provides important results on the probability distribution of genealogies (and hence on their shape) arising as a limiting case under a class of population genetics models such as the Wright–Fisher and Moran models. One major result of the standard coalescent is that in a sample of size n, the time T_n during which there are n lineages (i.e., until the first two lineages coalesce) follows an exponential distribution of parameter $\lambda_n = n(n-1)/4N_e$, where N_e is the effective population size. Its expectation is $E[T_n] = 1/\lambda_n = 4N_e/n(n-1)$.

Importantly, coalescent times are functions of N_e and n, and are independent of the mutational process, so long as neutrality can be assumed. After the first coalescent event, the number of lineages decreases to $n-1$ and the following coalescent time is sampled from the *new* exponential distribution with parameter λ_{n-1} and expectation $E[T_{n-1}] = 4N_e/(n-1)(n-2)$. This process continues until the most recent common ancestor (MRCA) of the sample is reached. The time to the MRCA represents the height of the gene tree and has an expectation of $E[T_{\text{MRCA}}] = E[T_n] + E[T_{n-1}] + \cdots + E[T_2] = 4N_e(1-1/n)$. Thus, for reasonably large sample sizes, $E[T_{\text{MRCA}}] \sim 4N_e$ at equilibrium, and the T_{MRCA} of the *sample* is nearly equal to the T_{MRCA} of the *population*. The structure of this null-model tree is interesting as most of the coalescent events take place near the branches tips. For $n = 50$, coalescence times will vary, in expectation, by more than 3 orders of magnitude, with the first 25 and 35 coalescent events taking place in the first 2 and 5% of the tree's height, respectively. In contrast, the last coalescent event has an expectation of $2N_e$, that is, half the tree's height. The tree is thus typically dominated by the last two branches in an equilibrium population.

For populations with monotonic size changes, it is straightforward to infer expected tree shapes (Figure 1). An expanding population can be seen as having its N_e decreasing backward in time. Thus, expected coalescence times will also decrease with N_e. Hence, compared to a stable population of similar size today, coalescent events will concentrate around the MRCA, producing a "starlike" tree. By contrast, in a declining population, coalescence times are moved toward the present and the tree has a "comblike" shape. Assuming a high enough mutation rate, a starlike tree is expected to produce alleles that have evolved more or less independently since the MRCA and mutations will accumulate along branches of similar lengths. Hence, going back to mismatch distributions, we expect them to be unimodal and roughly Poisson-like (Slatkin and Hudson, 1991). By contrast, stable populations are expected to produce ragged mismatch distributions with at least two modes (since the tree is dominated by the last branches).

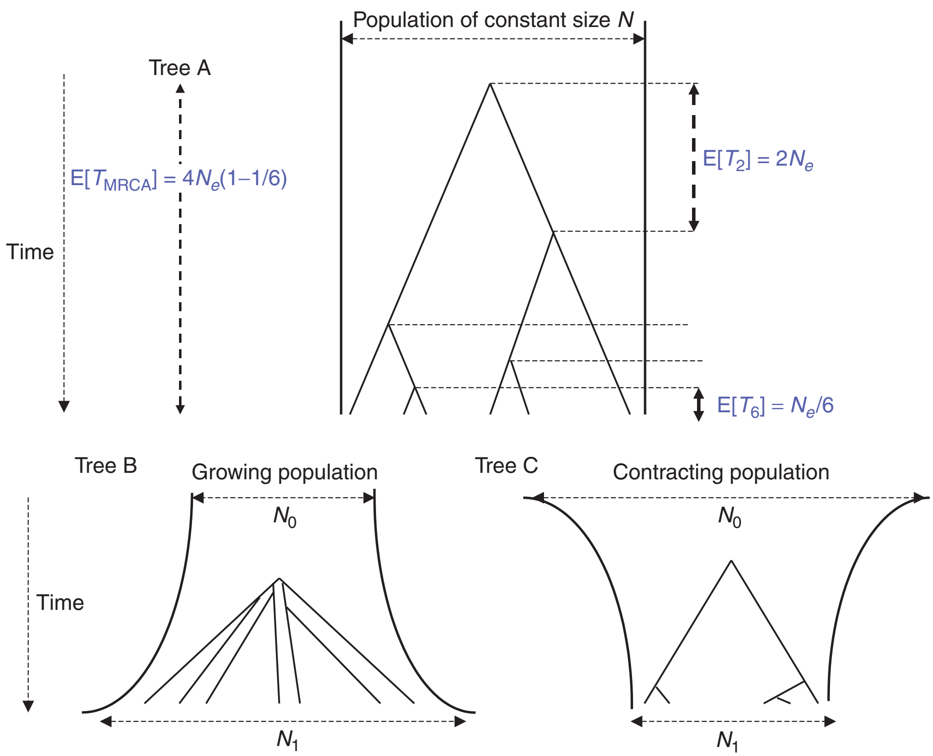

Figure 1 Coalescent trees. Tree A is the tree expected under a simple Wright–Fisher model (population size constant, no selection). Tree B is expected under a population growth. Tree C is expected under a model of population contraction

It may be worth noting that we presented the properties of the true gene trees, which are usually unknown. In practice, trees have to be estimated using polymorphism data, which are dependent on the mutation process and the time since the MRCA. When the total number of mutations is low, we may not be able to separate a starlike from a comblike tree. Similarly, when the number of mutations is high in a starlike phylogeny and if homoplasy is important, as in microsatellite loci, similar alleles may be generated by long branches that will reduce the expansion signal by creating false short branches.

Despite being a limiting case, the coalescent is extremely popular among population geneticists because it is fairly robust to details of life history (Donnelly and Tavaré, 1995), and coalescent simulations are also extremely fast (samples, rather than populations are simulated). The standard coalescent has also been extended to account for population structure, recombination within the locus of interest, and different forms of selection, a thorough review of which is given by Nordborg (2001).

In the next section, we discuss some of the ongoing research on population genetic modeling and some of problems that still need to be addressed in coalescent-based modeling.

3. Improving the use of genetic information: increasingly complex models for increasingly complex data

3.1. Bayesian and approximate Bayesian methods: the use of rejection, importance sampling, and Markov chain Monte Carlo algorithms

Following Felsenstein's (1992) remark that summary statistics discard most of the information present in genetic data, recent genetic modeling has seen the development of a number of statistical approaches that try to extract as much information as possible from the full allelic distributions.

Likelihood-based approaches aim at computing the probability $P_{\mathrm{M}}(D|\theta)$ of generating the observed data D under some demographical model M, defined by a set of parameters $\theta = (\theta_1, \ldots, \theta_k)$. This probability, which can be seen as a function of θ (since M is assumed and D is given) is the likelihood $L_{\mathrm{M}}(\theta|D)$, or simply $L(\theta)$. Some methods try to find the θ_i values that maximize $L(\theta)$, and use these maximum likelihood estimates (MLE) for the parameters of interest. Other likelihood-based approaches take a Bayesian perspective and try to estimate probability density functions for these parameters (rather than point estimates). Using Bayes formula, this can be written as:

$$P_{\mathrm{M}}(\theta|D) = P_{\mathrm{M}}(\theta) * \frac{P_{\mathrm{M}}(D|\theta)}{P_{\mathrm{M}}(D)} = P_{\mathrm{M}}(\theta) * \frac{L_{\mathrm{M}}(\theta|D)}{P_{\mathrm{M}}(D)} \tag{2}$$

Since the denominator $P_M(D)$ is constant, *given* the data, $P_M(\theta|D)$ is proportional to $P_M(\theta) * L_M(\theta|D)$. In the Bayesian framework, $P_M(\theta)$ summarizes knowledge (or lack thereof) regarding the θ_i *before* the data are observed and is referred to as the prior. $P_{\mathrm{M}}(\theta|D)$ is the posterior and represents new knowledge about the θ_i *after* the data have been observed. The posterior is thus obtained by weighting the prior with the likelihood function. While the use of priors involves some subjectivity, it has the advantage of making clear and explicit assumptions about parameters, rather than assuming point values for, say, mutation rates or generation times, as has often been the case in the past, for instance, to date population split events (Goldstein *et al*., 1995; Chikhi *et al*., 1998; Zhivotovsky, 2001).

The two previous approaches require the likelihood to be computed. It is theoretically possible to use coalescent simulations to generate samples under complex demographic models, and hence estimate $P_{\mathrm{M}}(D|\theta)$ for many parameter values using classical Monte Carlo (MC) integration. In practice, however, these probabilities are so small that they cannot be estimated in reasonable amounts of time for most sample sizes (Beaumont, 1999). Efficiency can be improved by using importance sampling (IS), which aims to sample gene trees as closely as possible from their conditional distribution, given the data, thereby avoiding most of the genealogies that would be sampled in classical MC simulations (Griffiths and Tavaré, 1994; Stephens and Donnelly, 2000). Another computer-intensive approach that has had some success in making inferences about demographic history is Markov chain Monte Carlo (MCMC), in which a Markov chain is simulated whose stationary distribution is the required Bayesian posterior distribution. Example

applications to human population data include estimation of the amount and direction of gene flow in equilibrium models of migration-drift balance (Beerli and Felsenstein, 2001), the relative contributions of source populations in an admixture model (Chikhi *et al*., 2001), and the inference of ancestral size and splitting of human and chimpanzee populations (Rannala and Yang, 2003). A particularly exciting application of MCMC is in a model of migration with population splitting (Nielsen and Wakeley, 2001; Hey and Nielsen, 2004), which has recently been used to infer aspects of the recent demographic history of chimpanzees (Won and Hey, 2005), and undoubtedly will have useful applications in humans.

Most likelihood-based methods have not yet had the impact one would have expected. This is due to the fact that for most interesting demographic models the likelihood cannot be computed or approximated. Also, the computations are extremely time-consuming and hence cannot be applied to the increasing size of modern data sets. An exception here is computer-intensive methods for detecting admixture and cryptic population structure from multilocus genotypic data (Dawson and Belkhir, 2001; Pritchard *et al*., 2000; Falush *et al*., 2003), but these are based on relatively simple approximations that do not include genealogical structure. However, they do point to one possible avenue in population genetics, the approximation of complex genealogical models, the parameters of which can then be inferred considerably more easily. Examples in this vein are the development of PAC likelihood (for product of approximate conditionals) to simplify inference with recombining sequence data (Li and Stephens, 2003), in which the coalescent is approximated by a simpler genealogy with more tractable analytical properties; the use of composite likelihood methods (Wang, 2003; McVean *et al*., 2004), where the full likelihood is reduced to simpler components that are treated as independent and multiplied together.

An alternative to the likelihood-based methods that use all the data is the development of approximate likelihood methods that measure summary statistics from the data, and then use simulations to find parameter values that generate data sets with summary statistics that match those in the data most closely. Data are simulated according to a model or set of models for a wide range of parameter values, either using a regular grid (e.g., Weiss and von Haeseler, 1998) or sampling from prior distributions (e.g., Pritchard *et al*., 1999). Parameter values that produce simulated data sufficiently close to the observed data are used to estimate the likelihood (Weiss and von Haeseler, 1998 on mtDNA data) or construct posterior distributions (Pritchard *et al*., 1999, on linked Y chromosome microsatellite data). For instance, Weiss and von Haeseler (1998) used the number of segregating sites S and π to measure similarity between data simulated under a model of population size change (exponential increase or decrease versus stability) and observed data. They accepted the ith simulated data (and corresponding parameter values) using the indicator function:

$$I_\delta(i) = 1 \text{ if } (|\pi_i - \pi| < \delta \text{ and } S_i = S) \text{ and } I_\delta(i) = 0 \text{ otherwise} \tag{3}$$

where δ is some arbitrary tolerance level or threshold (see below).

By varying the exponential rate, the time since the population size started to change and , they constructed a grid of likelihood values. They then computed the

ratio to the highest value to define confidence intervals. Applying this approach to a Basque sample, they found virtually no support for a model of constant or decreasing population size. The best support was for a recent exponential increase from an originally small population, which is in agreement with the relative isolation of Basques from other European populations.

Pritchard *et al*. (1999) also analyzed models of exponential size change, but used three summary statistics, the number of different haplotypes, the mean (across loci) of the variance in repeat numbers, and the mean heterozygosity across loci. They used an indicator function I_δ such that for the ith simulation $I_\delta(i) = 1$ if the three relative differences $|P_{SIM} - P_{OBS}|/P_{OBS}$ are less than the tolerance δ, where P stands for any of the three parameters, and $I_\delta(i) = 0$ otherwise. They applied this method to data from different continents and found strong support for a model of population growth for the whole world population (despite genetic differentiation between continents), and for East and South Africa, America, Europe, East, and West Asia but not for West Africa or Oceania. They also found that there was a huge uncertainty on t_0, the time at which populations started to increase, and on T_{MRCA} values, confirming as well that t_0 and T_{MRCA} are generally very different. Mean T_{MRCA} values around 40 KYA had confidence intervals ranging between ~10 and more than 100 KYA. Another important result for the interpretation of results obtained under different genetic models was that constraints on allelic sizes could lead to significant changes in T_{MRCA} values (but not so much on t_0). For instance, the higher end of the T_{MRCA} confidence interval could move from ~120 to ~320 KYA when constraints were accounted for.

Bayesian versions of these summary-statistic methods (such as Pritchard *et al*., 1999) have recently been dubbed "approximate Bayesian computation (ABC)" (Beaumont *et al*., 2002; Marjoram *et al*., 2003), and made more efficient. For example, Beaumont *et al*. (2002) have suggested improvements by applying a rejection algorithm as above, weighting the accepted parameter values according to their distance to the observed data, and correcting for the relationship between the parameter value and summary statistics in the vicinity of those calculated from the observed data. Marjoram *et al*. (2003) have proposed an MCMC algorithm where the acceptance or rejection of an update depends on whether the data or summary statistics thereof that arise from the update are within some distance of those observed in the data.

ABC methods are extremely flexible since they can be applied to any demographic model under which data can be simulated. It is also easier to add nongenetic information into the priors, which could be particularly relevant for integrating archaeological data into genetic modeling. Limitations stem from the difficulty to decide which summary statistics should be used and how the value of the tolerance δ influences inference. Little has been done on these issues, but Beaumont *et al*. (2002) found that the improved ABC algorithm was little affected by δ values whereas the simple rejection approach was strongly influenced.

Summary statistics do not need to be used in a likelihood framework. An example here is the study by Pluzhnikov *et al*. (2002) in which the distribution of summary statistics for different parameter values is estimated by simulations, and then compared with summary statistics in the data. Using this approach on multilocus sequence data, they found that European and Chinese populations did not

fit with a stable population or exponentially growing population model. Recent work by Akey *et al*. (2004) studied the behavior of four summary statistics, Tajima's D and Fu and Li's D^* and F^*, and Fay and Wu's H, under the standard neutral model and four additional demographical scenarios (an exponential expansion, a bottleneck, a two-island model and an ancient population split). They computed a score function on the basis of the absolute difference in average summary statistics from simulations under specific demographic scenarios with those in the data, and then chose parameter values that minimized this score. This was carried out for 132 genes sequenced in African-American and European-American samples and they were able to (1) estimate parameter values under different scenarios, (2) select reasonable scenarios for the different data sets, and (3) detect loci potentially under selection (outliers). For instance, they found that the European-American data set was most consistent with a bottleneck occurring 40 KYA, whereas the African-American sample was most consistent with either an expansion or an old and strong bottleneck. An interesting result is that out of the 22 loci potentially under selection under a standard model, only 8 were found to be outliers in the other four scenarios, and were termed "demographically robust selection genes". In other words, the demographical history of populations can potentially account for many outlier genes, which could be interpreted as being under some form of selection based on departures from the standard neutral model. This study also showed that most of the deviations from neutrality and all the "demographically robust selection genes" were not shared by the European- and African-Americans and was interpreted as reflecting potential local adaptations. A similar approach based on mismatch distributions and a set of demographic models was followed by Marth *et al*. (2003).

As indicated by the study of Akey *et al*. (2004), summary-statistic approaches can be useful for detecting selection on individual loci or genomic regions when a large number of markers are analyzed. A recently productive area of analysis in this regard has been based on estimators of the parameter F_{ST}. This parameter, which is used to measure genetic differentiation between populations, can be interpreted as the probability that two genes chosen at random within a subpopulation share a common ancestor within that subpopulation. It is expected that neutral loci should follow some unknown distribution, and that outlier loci, potentially under selection, can then be detected, as originally suggested by Cavalli-Sforza (1966). It is possible to construct a null distribution of F_{ST} under simple models, typically island models, and see where the real data lie (Beaumont and Nichols, 1996). Another solution is to use large numbers of loci sampled randomly in the genome to account for the unknown demographic history (but common to all loci) as suggested by Goldstein and Chikhi (2002). The latter approach has been used for 26 000 SNPs in African, European, and Asians samples by Akey *et al*. (2002) who detected a number of outliers. It has also been used with microsatellite data on European and African samples (Storz *et al*., 2004), which has, remarkably, yielded similar patterns to that found by Akey *et al*. (2004). Indeed, the outlier loci all have substantially reduced variability in non-African populations, suggesting adaptive selective sweeps following the putative OOA expansion. Of course, these inferences are dependent on the demographic model assumed, and it may be possible, for

example, that during a wave of advance some loci may be carried all the way with total replacement while others may be lost and replaced by indigenous markers, in which case a complex demography could mimic selection (Eswaran *et al*. 2005).

3.2. Increasing the complexity of models and the size of the data analyzed

In recent years, there has been increasing recognition and awareness that most of the models used to infer ancient demography were too simple. In this regard, an original and interesting modeling framework was recently developed by the group of L. Excoffier (Currat *et al*., 2004; Ray *et al*., 2003), which allows explicit spatial modeling of genetic data in which ecological information can be incorporated. First, complex demographical scenarios can be simulated using digitalized geographical maps made of cells arranged in a two-dimensional grid with defined carrying capacities and friction values (expressing the difficulty in moving through them). Samples are chosen on the digitalized map and coalescent simulations can then be carried out to simulate the genetic data of the populations of interest. Theoretical expectations of a number of summary statistics can be obtained under widely different scenarios and compared to observed data. This framework was implemented in the SPLATCHE software (Currat *et al*., 2004) and it was used in its simplest form (i.e., assuming no environmental heterogeneity) to study the effect of geographical expansions and varying levels of gene flow on the form of mismatch distributions (Ray *et al*., 2003). Currat and Excoffier (2004) also simulated the most realistic model to date, of the demographic expansion of humans in Europe and their interaction with Neanderthals. In this model, a range expansion of modern humans starts in the Near East with local logistic growth and a higher carrying capacity for humans over Neanderthals (to model a better exploitation of the environment by humans). Conditional on the fact that no Neanderthal mitochondrial DNA data are observed in humans today, coalescent simulations are carried out for different levels of admixture. Thus, using a summary-statistic approach akin to ABC methods, Currat and Excoffier (2004) demonstrate that the maximum level of admixture between Neanderthals and humans was most probably much lower than 0.1% (for the female line). This value in orders of magnitude lower than the lowest bound found using coalescent simulations that did not incorporate population structure. Thus, this study shows just how incorporating spatial structure into modeling can provide extremely different conclusions on admixture estimates.

Similarly, one of the most disputed issues in human genetics has been the detection of ancient bottlenecks and patterns of population growth. Wall and Przeworsky (2000) tried to put some order in the rather confusing literature, and concluded that the signal for a population bottleneck followed by an expansion detected in the early 1990s was mostly limited to mtDNA and Y chromosome data, and hence probably the result of selection on these loci. A more recent review by Excoffier (2002) concluded that most of the data disagreeing with a population

expansion were from coding regions and could, therefore, be explained by balancing selection, as was suggested for the first time by Harpending and Rogers (2000). Thus, the signal for population expansion would actually be real. However, the balancing selection hypothesis predicts that regions of low recombination should exhibit high levels of genetic diversity, whereas Payseur and Nachman (2002) found exactly the opposite, namely, a positive relationship between local recombination rate and variability. Recently, this issue had a new development when Hellman *et al*. (2003) found that this positive correlation could actually be caused by a correlation between recombination and mutation rates. Thus, it appears that the complexity of patterns of genetic variation in the genome can hinder our ability to uncover patterns of ancient population growth (*see* Article 1, **Population genomics: patterns of genetic variation within populations**, Volume 1).

Even assuming that one concentrates on neutral markers, the literature on population growth has been rather confusing. Table 1 is an attempt at summarizing some of the modeling assumptions made regarding past population size changes. The point we would like to make with this table is that it is very difficult to compare quantitatively and even qualitatively the results obtained by studies when the demographical model assumed (exponential vs. sudden growth, with or without previous bottleneck) the markers analyzed (maternally inherited mtDNA vs. nuclear coding genes vs. paternally inherited Y chromosome haplotypes) and the statistical approaches differ that much.

Another level of complexity arises when one studies the temporal behavior of the summary statistics used to detect population size changes. For instance, Tajima's D, which is probably the most popular of all statistics used to detect population expansions and bottlenecks, may be transiently positive and negative depending on the severity of the population size change and the number of generations since the original demographic event. After a bottleneck, D values will first be positive, then become negative when the population grows again, before tending towards equilibrium (Tajima, 1989b; Fay and Wu, 1999). Moreover, D is affected in a complex manner by increasing complexity of the mutation model. Simulations have shown that mutation rate heterogeneity within a locus can lower S, which could either lead to apparent signals of population bottlenecks, in an otherwise stationary population, or hide real population expansion signals by pushing D values in the opposite direction (Bertorelle and Slatkin, 1995; Aris-Brosou and Excoffier, 1996). More recently, hidden population structure was also shown to generate spurious results. Indeed, Ptak and Przeworski (2002) have shown that the number of "ethnicities" in the samples analyzed was negatively correlated to D. This can be understood by noticing that more diverse samples tend to contain a higher proportion of rare alleles, when populations are differentiated. Given that different loci can have different $N_e s$, the temporal behavior of D could lead to apparently contradictory results depending on whether mtDNA or nuclear microsatellites are analyzed, as was indeed found (Harpending and Rogers, 2000). A similarly complex temporal behavior was found by Reich and Goldstein (1998) for their peakedness statistic or by Kimmel *et al*. (1998) for their "imbalance index", making interpretations of these summary statistics more difficult than one would like.

Studies such as that of Akey *et al*. (2004) or Currat and Excoffier (2004) point to the importance of modeling population structure. However, an issue that has

Table 1 Examples of mutation and demographic models used to infer ancient human growth patterns

	Demographical model				Initial conditions		Mutation model	Approach	Marker

received very little attention is the influence of population extinctions despite the fact that early human groups were probably small enough to be subject to local extinctions. As noted by Eller (2002) and others (Sherry *et al*., 1998; Goldstein and Chikhi, 2002), the conservation genetics literature has developed approaches and models that could benefit human population genetics modeling. Indeed, an argument often used against the MR and in favor of the RAO model is that human diversity is low and corresponds to an effective size of approximately 10 000. Assuming a subdivided population as in the MR model would lead to census numbers too low to be compatible with any version of the MR model, which would require humans to be present across the Old World. However, as Eller (2002) showed, the argument would not necessarily hold if one accounted for extinction rates. With an extinction rate of 10%, an N_e of 10 000 could be compatible with census sizes greater than 300 000 under a wide range of conditions. This census size could even be larger if one assumed some level of intragroup inbreeding, as is the case in current human groups. Thus, accounting for extinctions would make the MR model compatible with small N_e values. Even though Eller used a simple demographic model (the infinite island model of Wright which allows every population to be in genetic continuity with every other one), this clearly shows that realistic models including extinctions, inbreeding, and differential migration rates could well add unexpected arguments to an already long debate.

The patterns and temporal behavior of genomic diversity is also the focus of ongoing and important research. Indeed, it has long been recognized that demographic events can influence patterns of linkage disequilibrium (LD, the statistical association between alleles from different loci), and hence that strong LD between physically unlinked markers could be the signature of admixture events or bottlenecks (Ardlie *et al*., 2002; Stumpf and Goldstein, 2003; Chikhi and Bruford, 2005). In the last 20 years, it has become increasingly clear that recombination rates vary enormously in the human genome with recombination hotspots separated by regions of low recombination rates (Nachman, 2003; McVean *et al*., 2004). It has recently been suggested that this structure is not simply the stochastic result in a model of more or less uniform recombination rate, but rather, corresponds to what has been called the blocklike structure of the human genome (e.g., Jeffreys *et al*., 2001; Ardlie *et al*., 2002; Stumpf and Goldstein, 2003). There is currently ongoing debate as to whether blocks exist or not (e.g., Anderson and Slatkin, 2004). But it is clear that the patterns of LD observed in many human data sets could not be explained in a model of exponential expansion, which predicted that LD should not extend much over 3–5 kb around a particular marker (Kruglyak, 1999). Moreover, recent simulations have shown that the expected pattern of LD blocks is stochastic and that even when simulations explicitly assume an extreme variation in recombination rates, some regions may not exhibit a block-like structure depending on the demographic history of the population of interest (Stumpf and Goldstein, 2003). This led these authors to suggest that populations (and regions of the genome) could go through different stages from preblock through block to postblock structure, in a complex manner in which the variance in recombination rates and the demographic history interact. Since different genomic regions have been analyzed in different populations with varied demographic histories, this issue is likely to be discussed for some years.

4. Conclusion and perspectives

We have tried to present above the general principles underlying the use of genetic data to detect past demographical events and estimate parameters of interest. We have seen that there has been a clear tendency toward incorporating more complexity in demographical and mutational models. Larger data sets including many independent loci are also becoming available to the community. For example, Marth *et al*. (2003) used data from as many as 500 000 SNPs and concluded for a significant bottleneck signal in humans. These data represent new challenges for population geneticists. Indeed, the potential risk in using SNPs is the ascertainment bias associated to their nonrandom discovery and typing. SNPs are usually detected in small samples and tend, therefore, to present balanced allele frequencies, which is not representative of neutral variation (Wakeley *et al*., 2001; Marth *et al*., 2003). Recent studies have tried to account for this sampling bias effect (e.g., Nielsen *et al*., 2004; Wakeley *et al*., 2001; Marth *et al*., 2003) but more research needs to be done. Similarly, the sampling of "populations" has to be improved. For instance, in the Akey *et al*. (2004) study, it is not clear whether differences between African-Americans and European-Americans actually reflect adaptations. Indeed, simulations show that admixture is expected to increase significance in the tests realized. Akey *et al*. concluded that their result was contrary to the expectation since African-Americans are admixed. As it happens, present-day Europeans are the result of a significant admixture event during the Neolithic transition (e.g., Chikhi *et al*., 2002), whereas the admixture level observed in African-Americans is very recent and much more limited. Thus, it could be that differences between the two groups are actually the result of their differing admixture histories.

Another avenue of research currently underexplored is the development of statistical approaches to quantitatively compared models (Burnham and Anderson, 2002). Likelihood theory has been used to compare nested models (e.g., Marth *et al*., 2003) but still much work needs to be done. Other avenues include the use of genomic patterns of diversity (such as variable recombination rates and block-structure patterns). Data from ancient DNA (assuming that contamination can be avoided) will also need to be incorporated in models that allow for genetic data to be sampled at different times. Ongoing research indicates that it is already possible to do so (e.g., Drummond *et al*., 2002; Shapiro *et al*., 2004), but future models will have to incorporate population structure since it would be extremely misleading to assume (rather than infer) a genealogical continuity between present-day people and archaeological samples from the same geographical area. A number of graphical methods such as those introduced by Nee *et al*. (1995) and further developed by Strimmer and Pybus (2001) and others may represent interesting avenues as a first exploratory step. These authors noted that it is possible to convert rates of coalescent events inferred from reconstructed gene phylogenies into N_e values and display them through time together with the corresponding gene tree (Nee *et al*., 1995). These "skyline plots", representing variations of N_e through time since the sample's MRCA, appear to generate different plots under different types of population size changes (linear versus exponential versus logistic). Thus, they could be used to construct a limited set of alternative models before some of the methods described above are applied to the data. A major limitation is that they require the genealogy

to be inferred with little error, which is difficult as we have seen. Another similar approach was used by Polanski *et al*. (1998) who tried to infer the demographic trajectory of humans (assuming monotonic growth) using mtDNA.

At this stage, we would like to make some cautionary remarks on a number of tree- or network-based methods, which have had great success among archaeologists and molecular biologists, but not so much among population geneticists. Indeed, there appears to be increasing use of such methods to devise complex scenarios, with migrations in multiple directions, back migrations, expansions, and long-distance migrations. Many of these complex scenarios are often constructed using sets of linked markers such as mtDNA or Y chromosome haplotypes. From an evolutionary point of view, such markers behave as single loci (with a number of "independent" alleles). The evidence from approximate and full likelihood analyses, which should theoretically extract close to as much information as possible from the data, suggests that they are providing limited amounts of information, even when few demographic parameters are estimated (e.g., Weiss and von Haeseler, 1998; Pritchard *et al*., 1999; Chikhi *et al*., 2001). The problem is that many demographic histories can give rise to the same genealogy, and the same demographic history is compatible with many different genealogies. Simulations have shown that population events and tree nodes are very loosely related (Nichols, 2001). For instance, we noted above with the Pritchard *et al*. (1999) study that the time at which a population expanded had little to do with the T_{MRCA}. In human studies, the already limited information is further reduced by authors who arbitrarily concentrate on subsets (haplogroups). The geographic distribution of haplogroups is then used to describe a possible pattern of past migrations of human populations (*see* Article 4, **Studies of human genetic history using the Y chromosome**, Volume 1 and Article 5, **Studies of human genetic history using mtDNA variation**, Volume 1). It is not clear what assumptions such methods make and under which scenarios they might "work". It is possible that they could work if one posited that each movement of populations was involving an initial bottleneck followed by an expansion of population size, so that the genealogy would be constrained to follow the demography, and the pattern not blurred by subsequent drifts or admixture. Although it is feasible that this is an accurate description of human history in some regions, it has thus far not been demonstrated. Genetic data are potentially very useful but they may be much more limited than one would like. When single locus data are used, one should always account for the possibility of a huge variance of the coalescent process, particularly when the underlying demography follows the assumptions of the standard coalescent. In this case, for instance, the variance of the T_{MRCA} is approximately $2.3 * N_e$ for reasonable sample sizes. This means that independent loci, representing independent draws from the same demographic history, are not expected to have similar gene trees or T_{MRCA} values. However, the stable population case represents an extreme, and other demographic histories, for example, expansion, will yield more similar genealogies among loci. Network-based methods are appealing because they are visual and easy to use, but it should be clear that it has not yet been demonstrated that they could provide statistically sound inferences (e.g., Knowles and Maddison, 2002). Their popularity is largely the result of a lack of credible alternative methods for complex modeling of genetic data. However, as

demonstrated in this article, the picture is now changing, and we can look forward to an exciting and challenging era based on parametric modeling of genetic data.

We hope that we have convinced the reader that it is a very exciting period to live in. A period in which the complexity of patterns of genomic diversity and of demographic trajectories of human groups is still to be discovered and explored. The field of human population genetic modeling provides, in many ways, richer research avenues than we could have imagined 20 or only 10 years ago.

Specialist Review

Homeobox gene repertoires: implications for the evolution of diversity

Claudia Kappen
University of Nebraska Medical Center, Omaha, NE, USA

1. Introduction

With the completion of sequencing the DNA of numerous entire genomes, a comprehensive analysis of gene repertoires in evolutionary perspective becomes possible. Of particular interest are those types of genes that are thought to be responsible for, or contributing to, the evolutionary changes that manifest themselves in the various distinct species. One of the prominent classes of such genes are the homeobox genes, the developmental control genes that play a role in the formation of and cell differentiation in multiple tissues in organisms as diverse as plants, yeasts, and animals (Akam *et al*., 1994; Banerjee-Basu and Baxevanis, 2001; Kappen, 1995; Kenyon, 1994).

Homeobox genes encode transcription factors with a DNA binding domain (the so-called homeodomain) (Gehring *et al*., 1990), and have been shown to control the patterning and development of multiple tissue systems in animals (Tautz, 1996), including axial patterning in embryos, and of derivatives of all germ layers: nervous system in worms, flies, and vertebrates; mesodermal derivatives, such as heart and muscle in flies and vertebrates; and skeleton and skin in mammals, as well as endodermal derivatives, such as lung, pancreas, and gut in vertebrates. Furthermore, tissue differentiation in the hematopoietic system, kidney, and skeleton of vertebrates is controlled by homeobox genes, and they have been shown to be involved in cancer (Abate-Shen, 2002, 2003; Cillo, 1994; Cillo *et al*., 1999). Experimental as well as genetic changes in the function of homeodomain transcription factors alter embryonic development, tissue function, and cellular differentiation, thus making them excellent candidates for substrates of changes in the evolution of species with differences in these processes.

In plants, homeobox genes are also involved in patterning during development, but the divergence of gene sequences and function make it difficult to construct a conceptual equivalence of plant and animal homeobox genes. In fact, it is now well established that – while transcription factors encompass from 2 to 5% of the genome – the repertoires of homeobox genes in plants and animals are essentially distinct (Meyerowitz, 2002; Riechmann *et al*., 2000; Kappen, unpublished data).

For the purpose of this article, I will therefore focus on animal homeobox genes, and most specifically on those genomes for which complete sequence with appropriate annotation quality is available (*Caenorhabditis elegans*, *Drosophila melanogaster*, *Mus musculus*, *Rattus norvegicus*, and *Homo sapiens*). The goal of this article is to determine how the complement and composition (collectively accounting for the repertoire) of homeobox genes in diverse species can inform about the evolutionary basis of diversity between species.

To this end, I will extend my previous analysis from one completed genome (Kappen, 2000a) to multiple genomes. The earlier results strongly favored a model of "intercalation" of genes within the limits of a given repertoire of homeobox sequences. However, with only one completed (worm) and one semicomplete (at the time) genome (fly) analyzed, several important questions remained unanswered: (1) Does the complement of homeobox genes in a species relate to its complexity in body patterning? (2) Is there an identifiable pattern of gene multiplication as species with increased homeobox gene number arise? (3) Does the diversification of the homeobox gene repertoire follow a common trend along the evolutionary trajectory? or, in other words, are homeobox genes generally under common evolutionary constraints? (4) Can the patterns of history in homeobox gene evolution inform us about possible future trends? I will attempt to answer these questions on the basis of qualitative and quantitative analyses of homeodomain repertoires across relatively large evolutionary distances.

This focus will implicitly miss out on the exciting recent evidence for rapid homeobox gene evolution within shorter evolutionary time frames (Chow *et al*., 2001; Maiti *et al*., 1996; Schmid and Tautz, 1997; Sutton and Wilkinson, 1997; Ting *et al*., 1998, 2001). However, these reports are largely restricted to individual genes or individual evolutionary characters. While such investigations into individual homeobox gene function are indispensable to precisely decipher the relationship of gene regulation, gene function, and phenotypic character evolution (Averof and Patel, 1997), they cannot inform about patterns of evolution at the whole-genome level. In the same spirit, I will refer to excellent recent reviews on the evolution of individual subgroups of homeobox genes such as the Hox, Pax, En, Cut, Meis, and Knox genes (Bürglin, 1998; Bürglin and Cassata, 2002; Galliot *et al*., 1999; Gibert, 2002; Holland and Garcia-Fernandez, 1996; Kourakis and Martindale, 2000; Reiser *et al*., 2000; Steelman *et al*., 1997; Zhang and Nei, 1996) in favor of considering entire repertoires of homeodomains in selected model organisms. The expectation is that genome analyses will uncover trends of evolution at the gene as well as systems level, and in this way contribute to knowledge that may allow us to derive predictions about future trajectories of evolutionary change.

2. The evolution of homeobox gene repertoires in animals

2.1. *Content and classification of homeodomains in major animal species*

From the earliest invention of the homeodomain in a single-celled ancestral organism, expansion of the repertoire to the order of 100 homeodomains in invertebrates

and even more in vertebrates was achieved by duplication and diversification (Banerjee-Basu and Baxevanis, 2001; Kappen, 2000a). Traces of ancestry may still be evident from the relationships of homeodomains within a given genome. The information that can be derived from analyzing genomic repertoires has implications for speciation as well as evolution of diversity. There is growing recognition that the gene repertoires within the animal kingdom are largely conserved (Rubin *et al*., 2000). Indeed, for many vertebrate homeobox genes, orthologs have been identified in worm and fly, and vice versa. From whole-genome repertoires, we can now establish the extent of overlap, determine whether species-specific (or, in a broader perspective, clade-specific) homeobox genes exist, and assess degrees of conservation and divergence.

To this end, I have supplemented prior collections (Kappen *et al*., 1989, 1993; Kappen, 2000a) of homeodomain sequences with recently completed genomes by using the search functions "homeobox", "homeodomain", "homeo box", "homeo domain", and "homeo" in the NCBI Genome Browser. Nomenclature discrepancies were resolved according to sequence identity or on the basis of experimental literature. Zebrafish and Xenopus were omitted from any analyses performed here to avoid complications from tetraploidy. Classification was done as described previously (Kappen *et al*., 1993) and is in concordance with existing accepted classification schemes (Bürglin, 1995). Content of homeodomain sequences from respective species within each subgroup was determined from the sequence compilation by hand. The criteria for clade-specific (unique) genes were: (1) lack of an ortholog in other invertebrate or vertebrate species, (2) selective presence only in vertebrates, and (3) minimum distance of the "unique" sequence from any other sequence class in the same genome by at least seven residues (Kappen *et al*., 1993).

The schematic summary of these data is shown in Figure 1. Of the total of 154 homeodomain sequence classes, 80 are unique to one clade, with 53 of those found only in vertebrates. The latter include a number of proteins that contain both zinc-finger domains and homeodomains, often with multiple homeodomains in the same protein that each belong to a separate class. Under the restrictive definition of class membership used here, 53 classes are shared between two clades and 48 classes are shared between all three. The number of shared sequence classes clearly exceeds a random distribution: under Poisson distribution, one would expect 154 units to distribute into 57 single clades, 28 into two clades, and only 15 into the triple-clade category. The much higher number of sequence classes shared between all clades demonstrates the strong evolutionary conservation. This makes it possible to analyze in detail the evolution for each of the classes that are present in all clades.

2.2. Sequence subclasses and their contribution to the repertoire

Within each genome (Figure 2), subclasses of closely related sequences exist, such as the Dlx and Pbx subclasses. The subclasses are often of different size in different clades, reflecting either clade- or species-specific duplication events (as in case of the Dlx class) or strong conservation of genes known to have been duplicated in an ancestral organism, such as in the case of the Hox genes. Conserved sequence

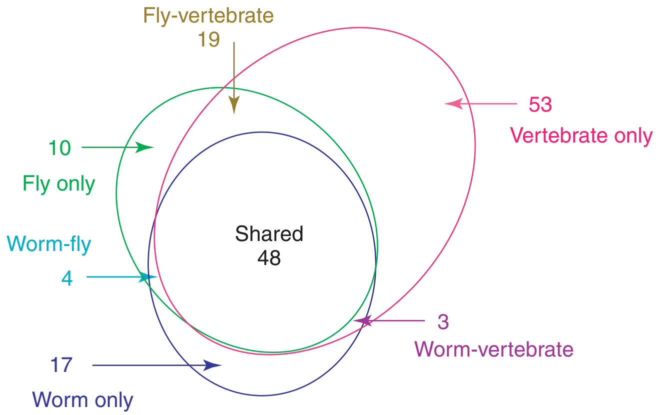

Figure 1 Overlap of homeodomain repertoires in major animal clades. The repertoire of homeodomain sequence classes for each animal clade is depicted as an ellipse whose area is approximately proportional to the number of sequence classes in each genome (72 for worm, 81 for fly, 123 for vertebrates). Areas of overlap depict sequence classes that are shared between clades

classes appear in all genomes analyzed here, as highlighted by same-color shading in Figure 2. In addition, clade-specific subclasses exist, such as a subclass of Zinc-finger homeobox genes that are restricted to the vertebrate lineage (Bayarsaihan *et al*., 2003). Genomes in separate clades (as represented by the model organisms) vary not only in total number of homeodomain sequences but also in relative contribution of each subclass to the overall repertoire (compare sizes of segment of a given color in Figure 2), motivating a more detailed analysis of genomic repertoires.

2.3. Distinct patterns of evolution for different subclasses of homeodomains

In particular, it is now possible to determine whether the increase in total number of homeodomains in vertebrates followed a specific pattern. For this analysis, I determined the number of sequences in each clade that belong to a particular sequence class. If the increase in total sequence number involved the entire genome uniformly, one would expect corresponding gene numbers in most classes. As Figure 3 shows, multiple scenarios are observed. There are sequence classes that contain the same number of genes in more than one clade, but more common are preferential expansions within one clade. When the subclass of the Hox genes – which has undergone quadruplication in vertebrates (Wagner *et al*., 2003) – is taken out of consideration, there is a general trend of doubling toward the vertebrate clade, providing the basis for the larger number of homeodomain sequences in vertebrate genomes. With this increase in gene number, the representation of most sequence classes within the genomic repertoire remains conserved (compare size of segments of same color in Figure 2), unless a subclass underwent disproportionate expansion

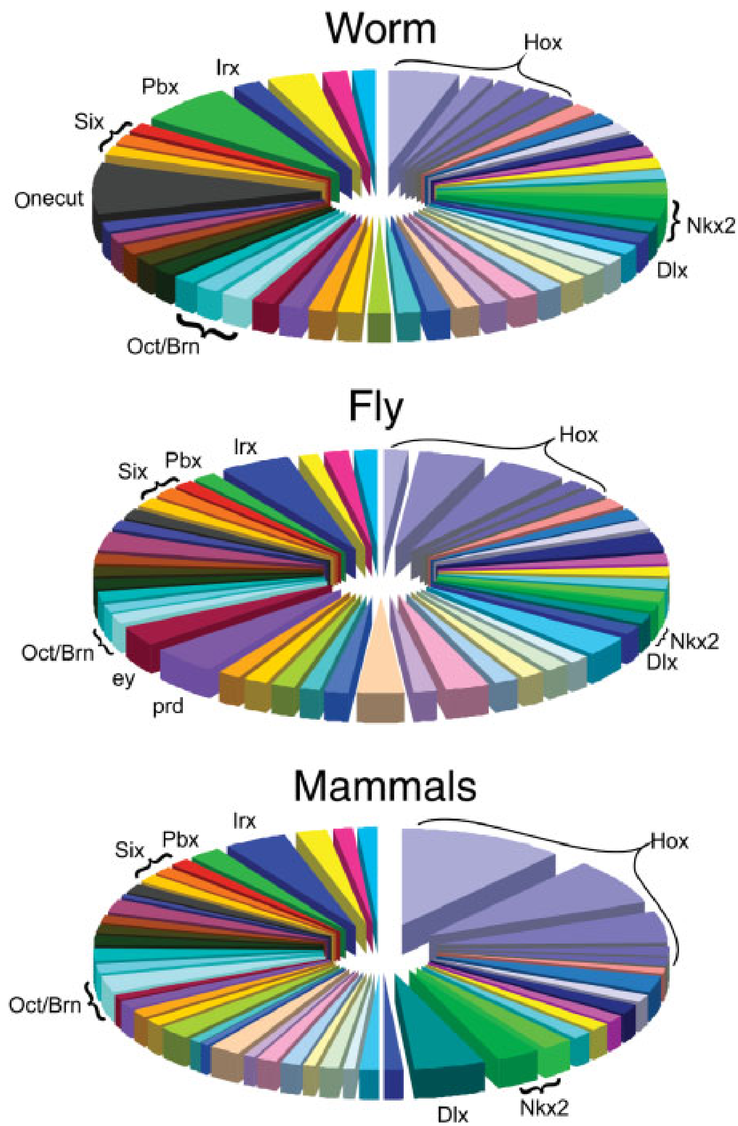

Figure 2 The repertoire of homeodomains in major animal clades. Each circle represents one genome with relative proportion of distinct homeodomain sequence classes shown as segments of a pie. Corresponding genes in the same subclass are labeled with the same color. It is evident that many subclasses are represented in all clades, but may be of different relative size in individual repertoires. For simplicity, subclasses that appear in only one clade were omitted. Several homeodomain subclasses are highlighted and specifically labeled: lilac shades: Hox-class homeodomains; green: Nkx 2 subclasses; teal: Dix class; turquoise: Oct/Brn homeodomains; red-orange-yellow: Six subclasses; green: Pbx class; blue: Irx class. The onecut (dark grey), prd (purple), and eyeless/Pax6 (wine red) subclasses show obvious clade-specific expansion in worm or fly, respectively. The Hox class contribution to the repertoire is enlarged in vertebrates

Worm	Fly	Human (*n*)
1	1	1 (9) 2 (17+2Hox) 3 (3) 4 (2) 7 (1)
1	2	1 (1) 2 (2) 3 (2) 6 (1)
1	3	2 (1) 6 (1) 7 (1Hox) 11 (1Hox)
2	1	3 (1) 4 (1)
3	1	1 (1) 16 (1Hox)
4	1	3 (1)
5	1	2 (1)

Figure 3 Patterns of homeodomain sequence distribution into subclasses. For each sequence class, the number of its gene members in each clade was determined. The occurrence of a given pattern was counted, and patterns are depicted here, in which each clade is represented by at least one gene. Seventeen such patterns were found (five patterns within the Hox subclass). In addition (not depicted here), five distinct distribution patterns with counterparts missing or unidentifiable in one clade were found seven times; thirteen patterns with one or more genes in only one clade accounted for the remainder, a large part constituted by the unique duplicated homeodomains in zinc-finger proteins in vertebrates. It is obvious that no single pattern dominates

or contraction. The results shown here demonstrate that there was no single mode of gene number expansion. Rather, it appears that each sequence class evolved by itself, suggesting independent mechanisms of selection.

2.4. Homeodomain subclasses evolved independently

This conclusion is supported by quantitative analyses. I performed two assays to define the degree of relationship of genes within the same sequence class: (1) pairwise distance analysis and (2) cladistic analyses.

For the distance analyses, I performed pairwise comparisons of sequences within each subclass, extending my earlier approach developed for individual species (Kappen, 2000a). Each amino acid difference was counted as 1 regardless of the type of amino acid residue found in either position. I have previously shown that the resolution achieved by this simple method is in good agreement with methods that use substitution matrices (Kappen, 2000a,b). Where a sequence in one clade corresponded to more than one in the other; all possible pairwise combinations were scored. Data are depicted separately for pairwise comparisons of clades. It is evident from the results for the worm-fly comparison (Figure 4a) that the distances between pairs of sequences vary from closely related (5 amino acid differences/60aa) to divergent. In fact, three major peaks are found, at 9, 14–16, and 29. Interestingly, the same patterns of distance distribution were found for worm-mammal comparisons (Figure 4b) and for fly-mammal comparisons (Figure 4c),

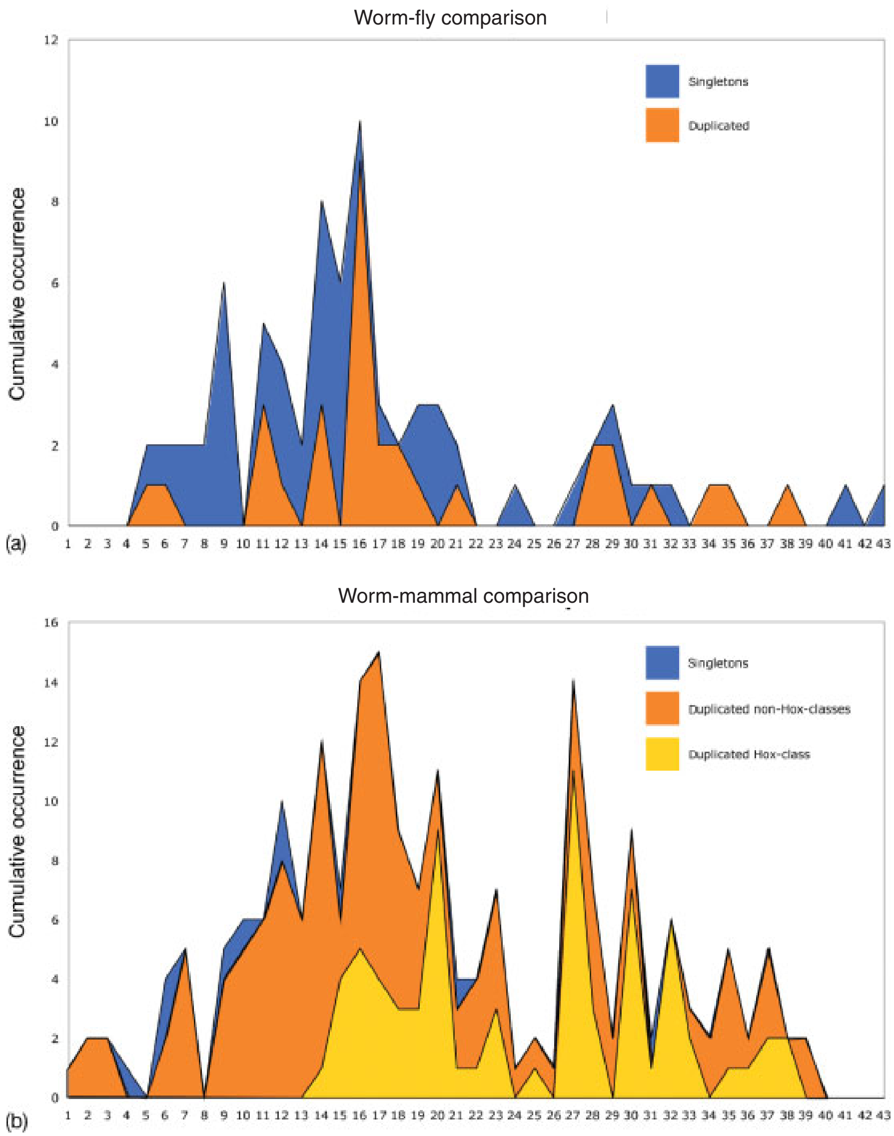

Figure 4 Distances between homeodomains within the same subclass. Pairwise comparisons were performed independently within each subclass and for each clade combination: (a) worm-fly pairwise comparisons; (b) worm-mammal pairwise comparisons; (c) fly-mammal pairwise comparisons. Datapoints contributed from sequences that have undergone duplication are added to single-gene (ortholog) comparisons. The cumulative height of each peak is the sum of all datapoints for a given distance. Color fills indicate blue: pairwise comparisons of corresponding homeodomains for which no duplicates exist in either clade (singletons); orange: pairwise comparisons of class members with each of their corresponding duplicate sequences from the other genome; yellow: pairwise comparisons of duplicate members of the Hox class

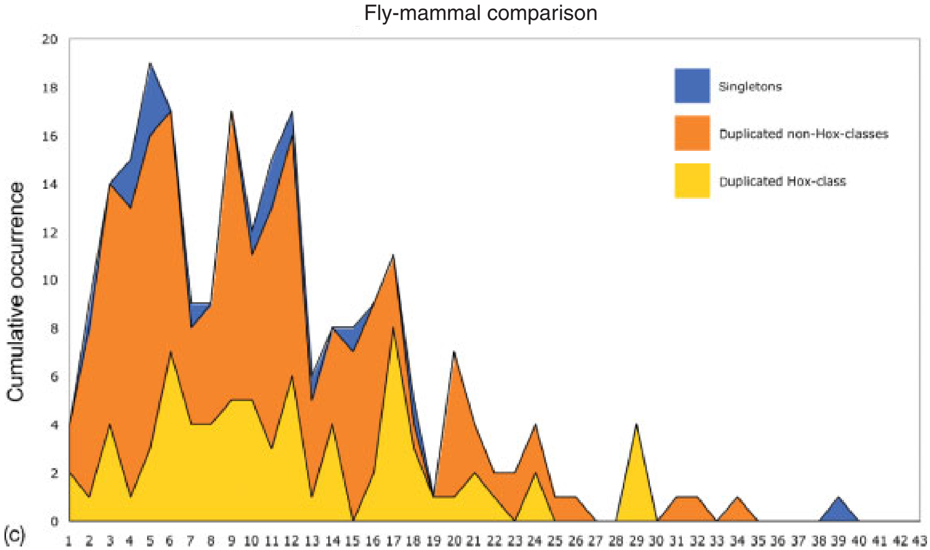

Figure 4 (*continued*)

although the distances were generally larger for worm-mammal comparisons and smaller for fly-mammal comparisons. The major peaks of worm-mammal distances are at 16–17, with shoulders at 20 and 23, and at 27; in contrast, fly-mammal distances peak at 4–5, 9–12, and 17. The difference in peak distances is largely contributed by the Hox subclass data, due to the divergence of worm Hox homeodomains. Accordingly, the similarity of Hox homeodomains between flies and mammals contributes to a shift toward shorter distances. The fact that distances distribute into recognizable peaks indicates that the sequences within some subclasses are more, or less, divergent than those in other subclasses. Finding this pattern for worm fly, fly-mammal, and worm-mammal comparisons suggests that the degree of divergence is a feature associated with a given subclass.

Several possible explanations can account for these data: Where subclasses have duplicates, these duplicates could have arisen at different times, with older duplicates allowing for more divergence than younger duplicates. About half (35/67 = 52%) of the data points of the worm-fly comparisons are for single orthologous sequence pairs, 47.8% from duplications. However, as the cumulative plot in Figure 4(a) shows, the distributions of data for singletons and duplicates are very similar, making it unlikely that duplicates would have a strong influence on the results. The more plausible scenario is that differential divergence reflects different selective pressure for distinct subclasses. This interpretation provides a scenario in which homeodomain sequence subclasses were under different evolutionary constraints – most likely related to function, although chromosomal structure has also been implicated (Wagner *et al*., 2003) as a selective force – and thus, subclasses evolved independently from each other during the divergence of worm and fly from their last common ancestor.

Interestingly, the same general pattern is found for the worm-mammal (Figure 4b) and fly-mammal comparisons (Figure 4c). Here, duplications in either clade after divergence from the last common ancestor account for 94.8% (worm-mammals) and 93.6% (fly-mammals) of the data points, and would be consistent with different time points for clade-specific duplications. However, since differential selection pressures in the different clades are also possible, distance analyses alone are not sufficient to resolve this aspect. What these results do show, however, is clear support for the conclusion that homeodomain subclasses evolved independently from each other.

The prediction from these results is that phylogenetic analyses would reveal the divergence of sequences within a subclass both with regard to sequence and timing of duplications, and with regard to degree of divergence. Therefore, we subjected separate subclasses to phylogenetic analyses using cladistics.

For the cladistic analyses, only those subclasses are informative where multiple sequences exist in at least two clades. From the data in Figure 3, 15 such cases are available. Gene trees were generated in PAUP in exhaustive (for <12 sequences) or "branch-and-bound" searches with Yeast (*Saccharomyces cerevisiae*) Matα2 as the outgroup. While this may bias the position of the root relative to each tree, it will have no influence on topology and branch length in the tree itself. Such trees are therefore suitable to assess relative divergence of subgroup members in comparison to other subgroups. The prediction here is that if all subclasses were under similar evolutionary pressure, the branching topologies and branch lengths should be largely congruent. At least for each subset of distinct distribution patterns, one would expect highly similar tree topologies and branch lengths. Alternatively, different topologies and varying branch lengths would further support the notion that subclasses evolved independently.

This latter scenario is indeed advanced by the results (Figure 5): Two cases exist of the distribution pattern 1,2,2 (worm, fly, mammals), the Barx and the En subclass, respectively (Figure 5a and b). In both, the topologies of the gene trees are similar, but branch lengths are quite different in that the En class mammalian sequences are closely related, while this is the case only for the fly sequences in the Barx class. Another group that has two vertebrate members is the prd subclass (Figure 5c). Here, the fly genes – although recognizable duplicates of each other – are not closely related, and the worm member is also quite divergent. The other subclasses also exhibit distinct topologies and divergence patterns.

An interesting corollary of the results in Figure 5 is that fly sequences show, in the majority of cases, greater affinity to vertebrate sequences than to worm sequences, highlighting what is believed to be the very derived nature of the worm genome.

Furthermore, the overall tree length is not directly correlated to number of members in the class: the onecut (Figure 5f) and Pbx (Figure 5h) subclasses each have eight members, with the latter tree being shorter than the former. Rather, tree length is greater with greater divergence of worm sequences, most prominently illustrated by the Pbx (Figure 5h), Meis (Figure 5i) and Irx (Figure 5j) subclasses: each of these is very compact with short branch lengths for mammalian and fly sequences. The comparison of these subclasses to the other groups also shows that duplicated homeodomains in vertebrates are divergent from each other to varying degrees,

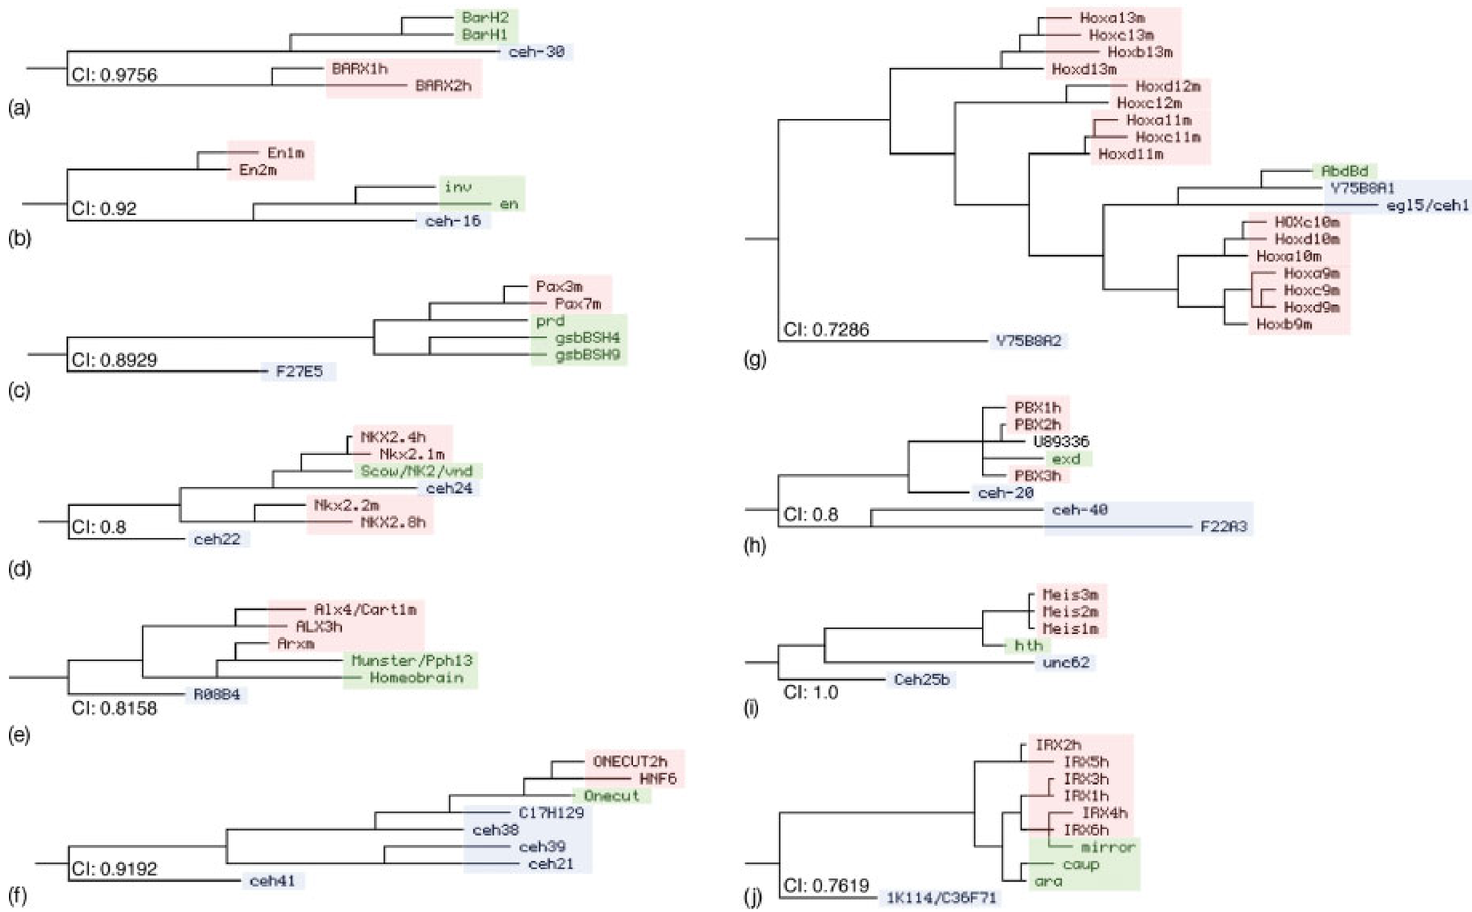

Figure 5 Phylogenetic patterns of homeodomain subclass evolution. Subclasses with multiple sequences in at least two clades were analyzed independently in exhaustive searches with either human or mouse serving as mammalian representatives. The consistency indices (excluding uninformative characters) were uniformly high, providing strong support for each tree. The somewhat reduced consistency indices for (g) and (j) reflect equally possible topologies of the same overall tree length with variable assignment of terminal branches due to a low number of parsimony-informative characters in the vertebrate homeodomain sequences of these subclasses. All trees were rooted to the same outgroup (Yeast Matα2) and scaled to the same scale for branch length. Shading denotes: red: mammalian sequences; green: fly sequences; and blue: worm sequences

from almost identical in the Meis group to greatest divergence in the Barx and Hox (Figure 5g) subclasses. These results are very consistent with the distance measurements. Thus, sequences in different subclasses evolved at different rates, arguing for distinct evolutionary pathways for each subclass.

2.5. *Duplication of homeodomains through genome-wide duplications: reconciliation of a controversy*

These types of results have – by others (Friedman and Hughes, 2003; Hughes, 1999) – been taken as arguments against the occurrence of genome-wide duplications in vertebrates. Indeed, the varying distances relative to the root of the branch points for mammalian homeodomains can be interpreted to mean that duplications of vertebrate homeodomains occurred at different points in time. One implication of this notion is that branch length is proportional to time; however, the scoring here was for replacement changes, not for silent nucleotide differences. Amino acid replacements alter protein structure, which in turn with altered function is subject to selection. Certainly, the distinct functional roles of the homeodomains in different subclasses provide the possibility that they could have been subjected to distinct selection pressures. Unfortunately, extending the analyses beyond the homeodomains does not improve resolution owing to the long divergence time since the postulated duplications. Noncoding sequences are also so divergent that no signatures of time elapsed since duplication remains (Kappen, unpublished). This is even more so for comparisons of duplicates in fly or worm, respectively. Rather than invoking consecutive independent duplications, different selection modes would also account for the three peaks of divergence found in the quantitative analysis (see Figure 4). As such, the different divergence rates at the protein level are not inherently inconsistent with genome duplications if independent evolutionary scenarios are applied to each class after duplication. If the duplications that created the vertebrate homeodomains indeed all happened at the same time, distances at silent nucleotide positions should be comparable between different subclasses.

In order to attempt to resolve the possible time points of duplication for the vertebrate homeodomains in different subclasses, I measured the distances between the vertebrate homeoboxes at the nucleotide level, taking into account only the silent sites. We have previously used this approach to determine the time point of Hox cluster duplication at 450 million years ago (Kappen *et al*., 1989), an estimate now well supported by experimental surveys of various chordate genomes. The prediction for these analyses is that equal rates of divergence at silent sites for independent subclasses predict the same evolutionary time point for duplication – such as through whole-genome duplication – while different rates have to be interpreted as reflecting independent duplications successive in time. This latter mode of duplication would indeed argue against whole-genome duplication in the origin of vertebrate evolution.

Figure 6 summarizes the distance measurements between duplicate mammalian homeobox nucleotide sequences. In all classes, numerous nucleotide differences were found, with measurements for the Engrailed and Nkx subclasses being

Subclass	Total changes	Replacement changes	Proportion of replacements/changes (%)	Proportion of silent changes/ possible silent sites (%)
Barx1/2	38	9	23.7	46.8
En1/2	26	3	11.5	37.1
Pax3/7	35	4	11.4	53.0
Nkx2 cognate pairs	26.5 ± 17.5	6.5 ± 4.5	17.8 ± 7.2	38.3 ± 11.7
Alx	46.7 ± 5.9	12.3 ± 3.8	26.4 ± 7.96	54.0 ± 9.0
Onecut1/2	47	15	31.9	55.2
Hox cognate pairs	28.7 ± 6.6	3.8 ± 2.2	13.2	57.1
Pbx	34 ± 3.6	2	5.95 ± 0.67	50.0 ± 5.9
Meis	34 ± 4.3	1.7 ± 0.5	4.8 ± 0.88	53.9 ± 6.4
Irx cognate pairs	11.3 ± 3.4	1 ± 0.8	7.5 ± 5.4	16.2 ± 4.1
Irx all	14.4 ± 4.8	5.6 ± 3.5	37.4 ± 19.3	15.4 ± 4.6

(a)

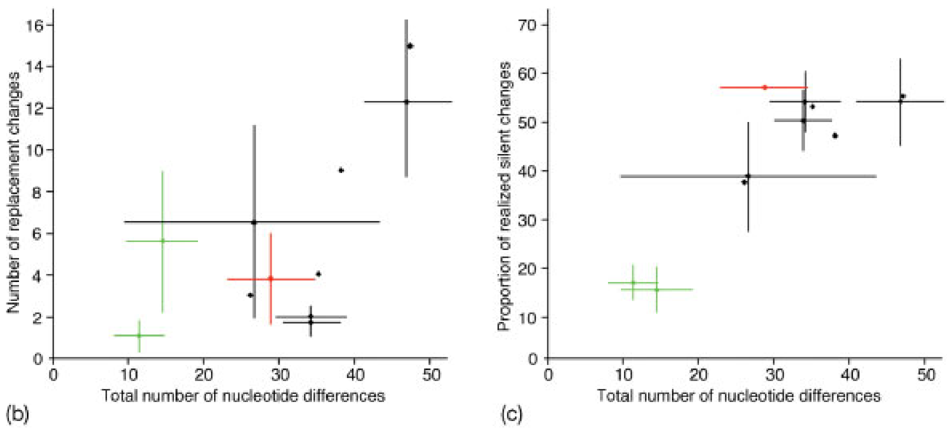

Figure 6 Analysis of nucleotide differences between homeobox sequences of different subclasses. (a) Pairwise sequence comparisons for the nucleotide sequences of the subclasses depicted in Figure 5. For all pairwise comparisons, the number of possible silent sites was very similar (between 57 and 66, with a mean of 62.1 + 2.5). Where genomic organization in clusters occurs (Nkx, Hox, Irx), pairwise comparisons were performed for the cognate paralogs. (b) Relationship of nucleotide differences to amino acid differences. (c) Relationship of nucleotide differences to silent changes. The data in (b) and (c) are plotted from (a). The data for the Hox subclass were taken from Kappen C, Schughart K and Ruddle FH (1989) Two steps in the evolution of Antennapedia-class vertebrate homeobox genes. *Proceedings of the National Academy of Sciences of the United States of America*, **86**, 5459–5463

comparable to previous results for the Hox subclass. The other classes, with the exception of the Irx subclass (discussed below), exhibit even greater distances. This corresponds to a larger number of replacements that change amino acid sequence of the homeodomain, although there was not a strict correlation (Figure 6b). The proportion of replacement changes ranged from about 5% (Meis and Pbx subclasses) to over 30% (onecut subclass). These results are reflected in the different terminal branch lengths in the amino acid–based gene trees for these subclasses (see Figure 5j, f, and i respectively), and underscore the differential degree of protein sequence conservation in distinct subclasses. However, the degree of sequence divergence at the protein levels is selection-dependent.

A selection-independent measure of sequence divergence is presented by silent nucleotide differences. The total number of silent sites was consistently around 60 in all subclasses, and the degree of nucleotide differences at silent sites was

quite similar for all subclasses (between 37.1 and 57.1%; except for the Irx class, discussed below). These data are most consistent with the interpretation that duplicated homeodomains originated at about the same time, having been subject to the same degree of divergence. Thus, while selective pressure on the protein level may have been different for homeodomain subclasses, the rate of silent change accumulation indicates a common time point for the origin of the duplications. Of all potential silent changes, approximately 50% are realized in any given pairwise comparison, arguing against saturation of the silent sites. By the same logic, the fraction of multiple hits at the same site – which I did not correct for in the present analysis – is expected to be too low to substantially affect the major conclusions. Thus, with a similar rate of silent differences, the divergence time since duplication must have essentially been the same, presumably because all duplicates arose at the same time point.

The fact that the rate of silent changes is very similar to that found previously for the Hox subclass (Kappen *et al*., 1989) allows us to place the duplication time point coincident with the Hox cluster duplications, with the emergence of the vertebrate lineage. After duplication, different subclasses then were subject to distinct selective forces. Thus, using a combination of nucleotide and amino acid sequence analyses and employing cladistic as well as distance analyses, I propose to reconcile the existing controversies and the apparent contradiction of conclusions from protein sequence and nucleotide sequences, respectively.

2.6. *The exception to the rule: evidence for an unidentified mechanism that constrains divergence*

However, a glaring contradiction to my conclusions is constituted by the Irx sequence subclass: The mammalian Irx genes are localized on two genomic clusters and are coordinately regulated with their position in these clusters (Peters *et al*., 2000). There are clearly fewer nucleotide differences between cognate members of the two Irx gene clusters than for any other gene duplicates (line 10 in Figure 6a), even compared to cognate paralogous genes within the Hox clusters (line 7 in Figure 6a). The nucleotide differences that are present account for amino acid changes to approximately the same degree as in Hox genes (13.2% vs. 7.5 ± 5.4%). However, the major discrepancy is constituted by far fewer silent differences between Irx cognate genes. One theoretically possible scenario would be that the Irx gene cluster duplicated independently from all the other subclasses, and later in evolution. Yet, the three ancestral Irx genes would have arisen before the evolution of the vertebrates (since cognates are present in all vertebrates sampled to date) and therefore could have diverged substantially, particularly at silent sites. This would be apparent in large silent nucleotide distances between noncognate pairs of Irx sequences. However, when all possible pairwise comparisons of Irx homeoboxes are performed (line 11, Figure 6a), the fraction of replacement changes increases (as expected), yet the rate of silent change accumulation is still exceptionally low (see red data points in Figure 6c).

There are several possible explanations for this finding: (1) The ancestral Irx genes arose very late in vertebrates – this is clearly contradicted by the presence of

multiple Irx sequences in chicken and zebrafish; sufficient time would have elapsed for the accumulation of silent changes. (2) The origin of three precursor Irx-like genes was independent in fly and vertebrate lineage, and preceded the Irx cluster duplications – the low number of silent differences between Irx noncognates is inconsistent with this scenario; the proportion of silent changes should be higher for noncognate pairs than for cognates. (3) Irx genes are subject to higher order "repair" processes or a fundamentally lower mutation rate than other homeobox genes. This could have to do with their unique organization in coordinately regulated clusters, but would differ from the Hox genes, which are also located in gene clusters. There is currently no evidence available, but chromatin structure, gene conversion, recombination events between Irx clusters, template-mediated repair, or constraint from functional sequences on the opposite strand would be plausible mechanisms. Then, unless one dismisses the entire methodology of silent site analysis as invalid, the results for the Irx homeobox subclass suggest the presence of yet undiscovered mechanisms that limit sequence divergence.

Taken together, these considerations suggest a unique modus of evolution for the Irx homeobox subclass that remains to be investigated. The evolutionary history of the majority of homeodomain subclasses, nevertheless, is consistent with prior hypotheses, most notably with the notion of genome duplications at the origin of the vertebrate clade.

3. Implications for the evolution of diversity

In response to the major questions asked at the outset of this study, the following conclusions emerge:

3.1. On relationship of genomic repertoire and organismal complexity

Does the complement of homeobox genes in a species relate to its complexity in body patterning?

At the gross level, the number of homeobox genes increases in vertebrates who have more complex body plans relative to flies and worms with simpler anatomy (Marshall *et al*., 1999). The repertoire of shared sequence classes also, at gross level, is very comparable between clades. Yet, each clade also harbors clade-specific sequence classes, and their relative contribution to the repertoire varies: clade-specific sequence classes make up 23.6% of all sequence classes in the worm, 12.3% in the fly, and 43% in mammals. Thus, in addition to strong conservation of shared repertoires, unique features are present and contribute to overall complexity, at least based upon sequence numbers and their distribution into subclasses. Yet, well-defined measures for complexity of gene repertoires are needed to unequivocally answer the fundamental question. From a sequence-focused viewpoint, parameters of divergence, repertoire composition, representation of duplicates and so on would all have to be considered in a formal definition of complexity.

Measures of biological complexity are even more difficult. Not only does tissue architecture vary, but even with apparently conserved molecular networks, flies and

worms undergo principally determined developmental processes that, in contrast, are subject to regulation in vertebrates (Davidson and Ruvkun, 1999). Certainly, vertebrate innovations have increased body plan complexity, and homeobox genes feature prominently in the development of these structures (Shimeld and Holland, 2000; Wagner *et al*., 2003), but which specific changes in gene repertoires are relevant to these innovations is less well understood (Szathmary *et al*., 2001).

In addition, more detailed studies are needed to elucidate the functional roles of clade-specific homeobox subclasses and subclasses with clade-specific expansions. It would be expected that such classes control the particular features of body plans in a given animal clade. Indeed, rapid divergence at the OdsH locus has been implicated in fly speciation events (Ting *et al*., 1998, 2001), but evidence for additional such examples is currently lacking. For vertebrates, it has been speculated that the expansion of the AbdB-like Hox subclass enabled limb development (Izpisua-Belmonte and Duboule, 1992); but the roles of these genes in primary axial development (Favier *et al*., 1996; Fromental-Ramain *et al*., 1996; Zakany *et al*., 1996) and cell-type-specific differentiation (Godwin and Capecchi, 1998; Rijli *et al*., 1995; Satokata *et al*., 1995) complicate the determination of which of their functions was primordial in evolution. Furthermore, the functional significance of clade-specific gene duplications and expansions in the homeodomain repertoire remains to be investigated.

3.2. On the mechanisms of homeodomain subclass expansion

Is there an identifiable pattern of gene multiplication as species with increased homeobox gene number arise?

The answer here is an unequivocal “no”. On the basis of qualitative, distance, and cladistic analyses, it becomes clear that the various homeodomain subclasses evolved independently of each other. Most notably, some subclasses enjoyed expansion in clade-specific fashion, suggesting biological roles in processes particular to this clade. Within the vertebrates, many subclasses contain duplicates that appear to have emerged at about the same time point as the Hox cluster duplications. This is consistent with the hypothesis of genome duplications at the origin of the vertebrates (Bailey *et al*., 1997; Friedman and Hughes, 2003; Holland *et al*., 1994; Pebusque *et al*., 1998). Independent analyses at level of nucleotide sequences for nine distinct homeobox subclasses strongly support the conclusion that expansion of vertebrate homeodomain subclasses could have been achieved by genome duplications.

Deviation from this scenario is found for the Irx subclass, either because of peculiar evolutionary history or because of particular chromatin features. The relevance of clustered organization for function of the Irx homeobox gene subclass remains to be established experimentally. Regardless of the outcome of these future studies, my complementary analyses of protein and nucleotide sequences demonstrate that conclusions based entirely on only one of these approaches may be biased and incomplete (Agosti *et al*., 1996; Marshall *et al*., 1999). In this regard, a thorough treatment of the controversy surrounding genome duplications will require parallel nucleotide and amino acid sequence analyses for multiple gene classes. This

may still be restricted to the most conserved domains of a gene, but the extension to multiple diverse gene families (Van de Peer *et al*., 2001) would likely overcome features peculiar to any given family, such as chromosomal position, clustering, chromatin structure, differential recombination rates of loci and the like. While an absolute estimate in terms of a molecular clock may be impossible to achieve, the relative rates of evolution at silent sites in various multigene families should be at least as informative as the analyses performed here for the homeobox gene sequences.

3.3. On the evolutionary trajectories of homeodomains

Does the diversification of the homeobox gene repertoire follow a common trend along the evolutionary trajectory; are homeobox genes generally under common evolutionary constraints?

The answer here again is an unequivocal "no". Qualitative analyses reveal different compositions of homeodomain subclasses in patterns that are not generalizable but appear specific to a given sequence subclass. Distance as well as cladistic analyses also establish distinct patterns and degrees of divergence. These distinct evolutionary trajectories argue for independent selection mechanisms for each subclass.

Relative to postulated ancestral genes (or, where available, sequences in early chordates), it is not possible to ascertain which of the two vertebrate duplicates can be considered "ancestral" or "derived" copy. This is also the case in worm, where the divergence of duplicates is greatest. The observed patterns of sequence divergence are thus not easily compatible with the idea of "freeze one – diverge the other" (Bailey *et al*., 1997; Ruddle *et al*., 1994; Van de Peer *et al*., 2001). On the other hand, the large distances of the clades included in the analyses presented here may obscure events on finer evolutionary time scale. Nevertheless, for vertebrates, the data do not provide much support for the "gene freeze" hypothesis.

Yet, at a time of rapid radiation and extensive diversification of species, such as in the pre-Cambrian prior to emergence of the chordate lineage, divergence may have been possible without immediate compromise of successful organismal development. In fact, it is intriguing that replacement of the majority of residues in the homeodomain with a uniform sequence of Alanines does not change regulatory specificity (in vitro!) as long as the N-terminal arm and the DNA binding helix 3 remains unaltered (Shang *et al*., 1994). Given that regions outside of the homeodomains are vastly different even in the corresponding (believed to be orthologous) genes in different clades, it remains to be investigated to which extent amino acid replacements account for changes in homeodomain function. Where attempted, replacement – in genomo – of one homeobox gene with a duplicate often rescues the majority of functions (Greer *et al*., 2000; Hanks *et al*., 1995; Zakany *et al*., 1996; Zhao and Potter, 2002), arguing for extended functional redundancy even for divergent nonhomeodomain sequences. The ability of fly and vertebrate homeodomain proteins to functionally substitute for each other (Malicki *et al*., 1990, 1993; McGinnis *et al*., 1990; Zhao *et al*., 1993) also argues against significant functional involvement of nonconserved protein domains. These

studies underscore the importance of the homeodomain – and, implicitly, of DNA binding – as its major function. The significance of amino acid residue changes in the evolution of a given homeodomain in different clades remains to be elucidated. One prediction from these considerations for human disease is that the most phenotypically relevant mutations would be expected to occur in or affect the function of the homeodomain.

3.4. *On the predictive aspects of molecular evolutionary analyses*

Can the patterns of history in homeobox gene evolution inform us about possible future trends?

Here, the limitations of focusing on major clades become most apparent: Clearly, in order to define evolutionary trajectories of specific homeodomain subclasses in any detail, it would be helpful to obtain the sequence of a given homeobox gene from as many species as possible. Then, it becomes possible to define changes that are unique to a given species, and, thus, uninformative unless associated with functional alterations. Conversely, changes common to multiple species can at least serve as a sequence trace of common ancestry, and possibly, of shared functional changes. Eventually, all manifest sequence differences in extant species can be classified as (1) tolerable and viable variations or (2) viable but functionally relevant replacements; detrimental changes will not be fixed in any population. Whether or not enough natural variations will be found to resemble a mutational series – in realo – remains to be seen, but such a dataset would clearly help in assigning functional relevance to particular residues.

The de facto possible variations resemble potential directions of future change for existing homeodomains, and structure predictions would help in eliminating – at least theoretically – from this vast reservoir those changes that will disrupt homeodomain structure. Knowing evolutionary trajectories would allow to map a pathway in sequence space, and the projection of this pathway would indicate potential future directions (Kappen, 2000a). This should presently be feasible for changes at single residues, but even less evidence is available on coselected residues; yet, cooperation of distant residues within the homeodomain for determining specificity is well established (Billeter *et al*., 1996; Gehring *et al*., 1994). Extended evolutionary analyses will thus complement and provide predictive power to experimental approaches.

4. Conclusion

With regard to organismal diversity, the present study advances a picture characterized by multiple distinct evolutionary trajectories for subclasses of homeodomains. Under this scenario, the different biological processes utilizing these homeodomain transcription factors are each themselves subject to distinct evolutionary forces. To determine how these forces integrate at the level of gene repertoires and individual organisms remains the challenge for future experimental and molecular evolutionary studies.

The present analyses also advance a theoretical framework that can be extended to virtually any genome and multiple gene families. My studies demonstrate the power of results generated from a combination of – applied in parallel to the same datasets – qualitative and quantitative methods. Through such combinations of complementary approaches, it should be possible in the future to precisely delineate the mechanisms in molecular evolution that produce changes at the level of individual development and organismic evolution.

Acknowledgments

I wish to dedicate this article to Dr Frank H. Ruddle, my postdoctoral supervisor, on the occasion of his retirement. His encouragement has been invaluable. I also thank my parents for fostering my curiosity and adventurous spirit, and Dr J. Michael Salbaum for continuing critical discussions and companionship in real-life adventures. Saralyn Fisher provided expert assistance in preparation of the manuscript.

Specialist Review

Geographic structure of human genetic variation: medical and evolutionary implications

Giorgio Bertorelle and Guido Barbujani
University of Ferrara, 44100 Ferrara, Italy

1. Introduction

This article is divided into three sections. In the first section we shall describe what we consider the main features of human geographic structure, that is, the fact that, on the average, two individuals living in the same geographic area are genetically more similar than two individuals living in different areas. Some common patterns observed at the global or local scale will be considered, and their possible origin will be discussed. In the second section, we shall summarize the consequences of the genetic structure currently observed in our species. Particular emphasis will be given to the known biomedical aspects, but the potential evolutionary implications will be also analyzed. Finally, in the third section, we shall discuss the possible future evolution of the human population structure, and how to predict it.

2. Human populations are genetically structured: how much, how, and why

Despite the recent appearance of our species and the ability and tendency to move not only to colonize new empty environments but also to exchange migrants among populations (*see* Article 4, **Studies of human genetic history using the Y chromosome**, Volume 1, Article 5, **Studies of human genetic history using mtDNA variation**, Volume 1, Article 2, **Modeling human genetic history**, Volume 1, Article 71, **SNPs and human history**, Volume 4) human groups from different geographic areas are often genetically distinct. The levels and patterns of this differentiation vary widely depending on the population, the genetic marker, and the sexes we consider. In humans, more than in other species, genetic structure is also unstable with time. Since the first colonization of the world by *Homo sapiens*, we probably never had a period of time long enough to establish a stable equilibrium of gene flow between local groups. Cultural and social changes, almost always associated with demographic effects, modified and continue to modify our population-genetic structure. But what is the situation today?

Roughly speaking, about 85% of the human genetic variation analyzed so far at the worldwide scale can be found, on the average, within a single population (Lewontin, 1972; Jobling *et al*., 2004; Barbujani, 2005; *see also* Article 1, **Population genomics: patterns of genetic variation within populations**, Volume 1). This figure is much higher than observed in several terrestrial mammals even at smaller geographic scales, where values smaller than 50% are not uncommon (e.g., Templeton, 1999). In other words, considering just this figure, population structure in humans appears limited: on the average, only about 15% of the genetic variation in our species occurs between populations, much less than observed, for example, in roe deer populations in Europe (Vernesi *et al*., 2002) or in common chimpanzee groups from different African forests (Kaessmann *et al*., 1999). This overall high level of population homogeneity can be explained by the history and the demography of humans: recent evolution, and high mobility. We all descend from some group of Eastern Africans, probably in the order of magnitude of 10^4 individuals (Takahata *et al*., 1995; Jobling *et al*., 2004) who dispersed and started to evolve in partially independent groups only in the last 60 000 years or so, and from which the current 6 billions of humans inherited their genes. However, the genetic structure of human populations would probably be stronger in a less mobile species. Genetic drift of allele frequencies due to founder effects during colonization or, in general, to small population size was probably the rule for much of our history. Only recurrent gene flow (mainly between neighboring groups) and massive migration processes (e.g., during the Neolithic transition) probably prevented a higher average divergence (at least in terms of allele frequencies) between human groups.

F_{st}, an index of genetic distance, can express differences between populations that measure the fraction of between-population variation over the total genetic variance. An average F_{st} of 15% can be considered low compared to other species, but still substantial since it indicates that human populations are, in fact, genetically differentiated. Only looking at specific populations, cultures, geographic areas, genes or markers, and time frames in more detail, we can try to understand the fine structure of human genetic variation and its implications.

There are many exceptions, but, as a rule, genetic variation tends to be geographically structured following a clinal or an isolation-by-distance (IBD) pattern. This means that the major patterns observed at large geographic scales can be described as a simple increase of F_{st} with geographic distance (Cavalli-Sforza *et al*., 1994; Relethford, 2004; Serre and Pääbo, 2004). The major mass migration processes responsible for the clines are believed to be the Paleolithic out-of-Africa dispersal of anatomically modern humans, and the dispersal of Neolithic farmers from areas of origin of agriculture in all continents but Australia (Bellwood, 2004). On the other hand, local gene flow between neighboring populations can produce the IBD pattern, that is, a decrease of F_{st} with increasing geographic distance in any direction, up to a certain distance where genetic exchange is minimal. Isolation by distance is probably a continuing process in virtually all-human populations. Both IBD and directional dispersal produce continuous genetic change (CGC), which implies that (1) F_{st} values can be much higher than 15% when geographically distant populations are compared, and (2) the definition of a higher hierarchical classification, that is, the identification of distinct groups of genetically similar

populations, is hard or not possible (Cooper *et al*., 2003). This last point, of course, does not mean that natural (sea, mountains, deserts, etc.) and cultural (language, tradition, behavior, etc.) barriers to gene flow do not create some level of genetic discontinuity between specific groups of populations. However, when different sets of markers are used to estimate the number of such groups or clusters, and to correctly reallocate genotypes to the cluster of origin, only broad continental groups (Africa, Eurasia, Oceania, and America) appear consistent across studies (Romualdi *et al*., 2002; Rosenberg *et al*., 2002; Bamshad *et al*., 2003). A recent study (Serre and Pääbo, 2004) even suggests that the sampling bias (populations are usually sampled on the basis of an a priori idea about the groups) could explain better this result than the real presence of continental genetic barriers. Additional samples more evenly distributed in the geographic space are needed, but present data suggest that CGC is the rule, and genetic discontinuities in space are the exception: major genetic grouping, including races (Barbujani, 2005), is not an accurate concept to classify humans. CGC does not mean that Africans and Asian are not genetically different, but it does mean that this difference can be low or high, depending on the geographic distance of the populations considered and on the set of loci analyzed. Therefore, the genetic and evolutionary meaning of these groups is limited.

An additional feature of the human geographic structure is the occurrence of single populations that strongly deviate from the general patterns reflecting the 85/15 apportionment of diversity and the effects of CGC. Geographic and cultural barriers, which strongly reduce reproductive contact with neighboring groups, usually coupled with small population sizes, can result in highly differentiated populations, or genetic isolates. A genetic threshold to identify such specific population histories has not been defined. However, populations which clearly emerge from the 85/15 + CGC patterns when several loci are considered (e.g., in a multivariate analysis), and have therefore pairwise F_{st} values higher than 15% in comparison with most of the other populations, can be considered genetic isolates. Typical barriers implied in the known cases (Cavalli-Sforza *et al*., 1994; Jobling *et al*., 2004) are the sea (e.g., Sardinians, Papua New Guineans), language (e.g., the Basques, who are possibly a Paleolithic non-Indo-European relic), life style (e.g., hunter-gatherer as African Pygmies) sometimes combined with high geographic isolation (e.g., the Lapps). Other groups, initially identified as genetic isolates on the basis of single marker analyses or high incidence of genetically inherited diseases (e.g., Ladin speakers, or Ashkenazy Jews, or Finns), revealed only an average degree of differentiation when investigated at the genomic level. Only multilocus analyses can estimate the real level of genetic isolation, since stochastic errors or gene-specific selection processes may confound the pattern in single-locus studies. For example, Ashkenazy Jews were recently classified together with Norwegians and Armenians when 39 markers were considered (Wilson *et al*., 2001) and Finns, who are characterized by a specific set of disease alleles, do not appear to have a specific genomic make-up (Cavalli-Sforza *et al*., 1994; Jobling *et al*., 2004). Similarly, when genetic isolates are identified, it is important to distinguish between "pure drift" isolates, that is, those recently diverged small populations with reduced variability and almost no specific alleles or mutations, from populations with a long independent accumulation of specific molecular variation. The former can be very

useful in mapping studies, but the latter contain certainly more information about the evolution of our species and our genomes.

The reduced fraction of genetic variation between populations, only about 15% on the average, is thus structured in a CGC pattern with outliers. This general view is mainly based on genetic polymorphisms such as mtDNA sequences, microsatellites, SNPs (*see* Article 71, **SNPs and human history**, Volume 4), Alu insertions, and classical electrophoretic markers, that is, on genome fragments, where selection is commonly believed to be either weak or absent. Most of the genome is constituted by regions of this kind (even though their possible regulatory functions are not completely understood). However, the geographic distribution of positively selected genes can be very different from the 85/15 + CGC + outliers predictions. Local adaptation and widespread (and similar) selective pressures produce, in fact, stronger and weaker geographic structure, respectively, and the genetic effects of selection can be very rapid (Hartl and Clark, 1997; Hendry and Kinnison, 2001). There is evidence, for example, that the mutation associated with the lactase persistence (that allows lactose digestion) in adulthood was selected in the last 10 000 years or so in pastoralist societies where milk drinking was an important part of the diet (Beja-Pereira *et al*., 2003; Coelho *et al*., 2005). This process produced an increase of frequency of the mutations associated with lactase persistence in these groups, and we observe now a higher population divergence (at this and probably at physically linked loci) when their descendents are compared with nonmilk drinkers. On the contrary, we expect that directional selection for the same allele in different populations, or balancing selection maintaining the same set of alleles in different groups, would produce lower-than-average population divergence. Genes showing low geographic structure, possibly because of balancing selection, includes *HLA*, *CCR5*, *PTC* genes (Cavalli-Sforza *et al*., 1994; Bamshad *et al*., 2002; Wooding *et al*., 2004). It is interesting to note that recent methods (Luikart *et al*., 2003), based on earlier ideas (Lewontin and Krakauer, 1973) reverse this approach; F_{st} is estimated for many DNA regions, and values falling in the upper and lower tail of the distribution are considered as suggestive of selective processes.

Finally, the fact that we have separate sexes has also an impact on human geographic structure. In a population with the same $N/2$ number of men and women, there are $2N$ copies of each autosomal DNA fragment, $N/2$ copies of each X-linked fragment, and $N/2$ copies of Y-linked and mtDNA fragments that can be transmitted to the next generation. In other words, random drift, which is negatively correlated with population size, is working at three different speeds in the same populations at these three classes of markers. Consequently, three different levels of population structure should be expected. In addition, the migration rate and the effective population size may differ in men and women. Most human populations are patrilocal, meaning that after marriage the men tend to stay in their birth place more than women, and our species was probably polygynous until recent times (Dupanloup *et al*., 2003), meaning that the number of transmitted Y chromosomes every generation was lower (and drift higher) than expected. Experimental data suggest that all these factors have been important, because the average level of geographic structure (say, F_{st}) in humans increases from autosomal to mtDNA markers (probably due to the different population size of the markers), and from

mtDNA markers to Y-linked markers (presumably due to different male and female behavior at reproduction) (Jobling *et al*., 2004). The relevance of the sex-specific migration patterns in shaping the genetic structure of human populations has been recently confirmed comparing patrilocal and matrilocal tribes of Thailand, where reverse patterns in mtDNA and Y-chromosome markers have been found (Oota *et al*., 2001; Hamilton *et al*., 2005).

In conclusion, the present structure of human populations is characterized not only by some general rules and established patterns, which tell us something about the major processes that shaped genetic variation, but also by several exceptions. The goal for the future is to increase our knowledge and understanding of the fine structure studying isolated groups and selected genes.

3. Population structure in humans: what does this imply?

We discuss now some biomedical and evolutionary implications of the genetic structure described in the previous section.

3.1. Biomedical implications

The geographic patterns at neutral markers, mainly affected by demographic and historical processes, are in part known and understood (see previous section), and can be easily investigated more deeply typing more populations and more markers. But what do we know about the genetic structure of disease alleles? Theoretical predictions and available data can be helpful.

Dominant deleterious mutations are rare, because their expression in all individuals with at least one affected chromosome rapidly drive them to extinction. Simple monogenic diseases with this type of inheritance are therefore rare, with a similar incidence in different populations simply regulated by mutation-selection equilibrium. Similarly, infrequent are the simple genetic diseases whose heterozygous carriers enjoy some selective advantage also over the healthy homozygotes (e.g., sickle cell anemia). In the few clear situations of this type, the population structure at these genes can be decoupled from the structure observed at neutral markers. Environmental differences in the selective pressure (e.g., the geographic distribution of malaria for the sick cell anemia) are, in fact, responsible of the observed population structure. On the other hand, when the fitness effects of mutations are expressed only in the homozygotes, or after the reproductive age, or are, in general, very limited as in the complex multigenic diseases (*see* Article 57, **Genetics of complex diseases: lessons from type 2 diabetes**, Volume 2; Article 58, **Concept of complex trait genetics**, Volume 2), the major factors acting on their frequencies are the same that affect neutral markers: demographic and historical processes. For example, the high frequency of several genetic diseases in the Jews is a consequence of their isolation and small effective population size. In other words, the major patterns of population structure described in the previous section are expected to be very similar also in most simple genetic disorders and in the numerous susceptibility alleles involved in complex genetic diseases.

There seem to be six main reasons why population structure should not be ignored in biomedical studies:

1. Priorities in genetic testing for different diseases (*see* Article 69, **Current approaches to prenatal screening and diagnosis**, Volume 2; Article 83, **Carrier screening: a tutorial**, Volume 2) or in treatments should consider the differences among populations. Given certain symptoms, the most likely disease depends also on the population affiliation of the affected individual. If data on the disease incidence are not known, genetically similar population at neutral markers can be used as proxy. If a population is a genetic isolate, specific disease risk alleles are expected.
2. Isolated and recently founded populations (e.g., Finns, possibly Sardinians or Icelanders) should be preferred in mapping studies by linkage disequilibrium (LD) in unrelated individuals and for studies of multigenic diseases in general. These populations are, in fact, comparable to large families, where genetic heterogeneity is rare (and so affected individuals carry the same mutation) and recombination did not have the time to disrupt the statistical association between the hunted gene and the flanking markers. The possibility to find such situations is clearly related to the fact that human populations are, at least to a certain degree, geographically structured, and in particular, genetic isolates exist (see Section (2)).
3. The common disease – common variant hypothesis (*see* Article 59, **The common disease common variant concept**, Volume 2) suggests that only few susceptibility alleles, at high frequencies in different populations, are responsible for common diseases (Chakravarti, 2001; Reich and Lander, 2001). However, the empirical evidence for this hypothesis is scant (Jobling *et al*., 2004). Several causal alleles are probably rare and population specific (Kittles and Weiss, 2003; Tishkoff and Kidd, 2004), and can also be embedded in a block structure (the partition of the genome in high LD regions, see for example Daly *et al*., 2001; *see* Article 74, **Finding and using haplotype blocks in candidate gene association studies**, Volume 4) specific of a population (Verhoeven and Simonsen, 2004). Both these factors indicated that LD mapping should not be performed in pooled samples of individuals of different origins, and we expect that different studies in single populations should be able to better identify different loci with higher power.
4. Spurious disease-marker associations are expected if sampling is not stratified by populations. If the frequency of a trait (the disease) is higher in a population, which is also genetically distinct at some neutral markers, and the population is jointly analyzed with the others (either because sample sizes are limited, or because the two populations coexist in the same area), the trait and the markers will result statistically, but not genetically, associated. For instance, a wide-genome scan carried out in the United States for the genetic determinant of β-thalassemia, a well-understood monogenic disease typical of Mediterranean Europe, might lead to the conclusion that many genes cause the disease. This is because the affected children (most of them from Greek and Italians families) might differ at several genome regions from the controls (representing the general US population).

5. The presence of genetically different groups implies that admixture, if occurs, can produce several consequences. This process was not uncommon during the history and prehistory of our species, for example, between hunter-gatherer residents and immigrating farmers in the Neolithic, or more recently between Native Americans, Africans, and Europeans in the Americas. One practical consequence is that mapping by admixture linkage disequilibrium (MALD; *see* Article 76, **Mapping by admixture linkage disequilibrium (MALD)**, Volume 4) is possible. This recently resurrected approach (McKeigue, 2005) exploits the transitory LD arising when distinct populations come together (of course trying to avoid the initially spurious correlations). From the point of view of the admixed population and individuals, genetic admixture produces a beneficial initial effect of heterosis (population-specific recessive deleterious alleles are not expressed in heterozygotes), and in general a decrease of the fraction of affected individuals at recessive disease alleles (since different allele frequencies result in less than average frequencies of homozygotes). On the other hand, outbreeding depression effects, although never demonstrated in humans, are possible in admixed populations. The frequency reduction of alleles positively and differentially selected in different environments (e.g., at the *MC1R* gene involved in pigmentation, or at the HLA system involved in immune response) may produce an increase of disease incidence in the admixed group. For example, skin cancer or vitamin D deficiency problems can increase when Caucasians and Africans mix, or infectious diseases can spread when populations adapted to different pathogen community come together. Also, coadapted combination of alleles at polygenic disease loci might be disrupted by admixture.
6. Exogenous molecules such as drugs should be absorbed and transported before acting, and metabolized and excreted after that. Several proteins are implicated during these phases, and their gene polymorphisms are related to differential efficiency (e.g., Meyer, 2004). On of the best-known examples is the gene *CYP2D6*, which encodes an enzyme that metabolize about 20% of the drugs in the market. Different genetic variants (that includes also variation in copy number) have different efficiency, where high and low efficiency result in reduced or toxic effects of the drug, respectively. The development of individual forms of pharmacological treatment based on the individuals' genotype is clearly the long-term goal of applied pharmacogenomic studies, but it will not be a possibility in the immediate future. In the short term, it is unclear whether priority in drug treatments could be based on population affiliation, because different studies yielded very different results as for the degree of geographical structuring among populations for drug-metabolizing genes (Bradford, 2002; Shimizu *et al*., 2003).

3.2. *Evolutionary implications*

Adaptive genetic change is the ultimate consequence of environmental pressures affecting the individuals' fitness, but often organisms respond to environmental change by physiological or cultural adaptation, the latter being very important in

primates, and especially for humans. Cultural adaptation can allow reproduction of individuals who otherwise would have reduced or zero fitness, and can drive to accumulation of deleterious or maladaptive mutations. However, (1) fitness is still reduced in individuals affected by several inheritable disorders, or in individuals with maladaptive allelic combinations at important genes such as HLA, especially in underdeveloped countries; (2) only few genes responsible for local adaptations are known, but we expect that more, still under selection in some human groups, will be discovered in the future; (3) human phenotypes selected in mating, cultural and social contexts, for example "attractiveness" or "trust", or "cooperation", or "intellectual abilities", or "novelty seeking", may have a genetic component (see e.g., Ding *et al*., 2002; Evans *et al*., 2004; Kosfeld *et al*., 2005), and are probably still under selection; (4) evolution is not only natural selection, culture might reduce selective pressures, but might increase other evolutionary processes; for example, linguistic barriers decrease the level of gene flow thus favoring the genetic divergence between populations. In addition, massive migration is bringing new alleles into new areas, and causing either admixture or the onset of local reproductive barriers, depending on the circumstances.

It is clear, therefore, that the genetic composition of our species is still subjected to evolutionary change, and it makes sense to ask what are the predictable evolutionary consequences of the current geographic structure.

High genetic variation is regarded as a positive asset of a species, both because it is associated with low inbreeding depression effect, and because the evolutionary potential is maintained. Does the global level of genetic variation in our species depend on the fact that we are not a single panmictic group? Surprisingly, population genetics theory has no unequivocal answer to this apparently simple question. Different results are obtained with different assumptions on the population structure model and the demographic parameters, and using different metrics to quantify genetic variation (Slatkin, 1987; Strobeck, 1987; Whitlock and Barton, 1997; Wakeley and Aliacar, 2001). Nobody can tell to what extent human populations were subjected to processes of local extinction and recolonization (that are expected to reduce genetic variation) or alternatively represented rather stable demographic units (whose fragmentation is expected to enhance genetic variation). However, if the extinction of differentiated groups is not frequent, as expected in a recent and expanding species (Foley, 1998), geographic structuring should result in the existence of relatively high genetic divergence. If this prediction is appropriate for humans, the overall geographic structure, limited but significant, positively affected the level of genetic variation in our species. Partly different gene pools would have evolved in diverging groups, and only rarely would such gene pools disappear by population extinction. The expected end result of a process of this kind is a global variation larger than in a panmictic population of the same size.

Be that as it may, the current geographic patterning of genetic variation suggests at least two additional considerations: (1) the widespread presence of clines (CGC), and the consequent absence of major genetic barriers, indicate that a process of speciation, clearly unlikely today, was probably not a possibility also during the whole history of our species; and (2) the presence of highly differentiated groups, either outliers in clinal pattern or populations at the extremes of the

clines, resulted in the localized occurrence of population-specific alleles. As a consequence, recent secondary contacts might result in the increase of infectious diseases, through a genetic out breeding depression effect (that can affect of course disease susceptibility as well as many other locally adapted traits) or in the diffusion of pathogens in immunologically naïve populations. However, similar to what happened in local breeds of domestic animals or local varieties of plants, differentiated groups might have preserved specific and unique portions of adaptive genetic variation, which might be useful not only in evolutionary but also medical terms. An example of that is the small community of Limone sul Garda where most individuals are genetically protected against heart diseases (Bielicki and Oda, 2002).

Finally, it is interesting to note that genetic and cultural factors can reinforce each other. Linguistic and genetic diversity, for example, appear broadly correlated over much of the planet (Cavalli-Sforza *et al*., 1988), but this is not due to the existence of genetic factors predisposing people to speak certain languages. On the contrary, there is evidence that language barriers, much like geographic barriers, reduce gene flow, so that the existence of cultural differences results in an increased genetic divergence (Barbujani and Sokal, 1990). In a sense, cultural differences (language differences being just the simplest traits to analyze) would create an opportunity for sexual selection to operate (Harpending and Rogers, 2000). Thus, in various contexts, cultural difference might additionally increase because contacts are limited by differences in traits related with mate choice. If this is true, we expect that the enormous importance of culture in our specie could have resulted in some populations in a species-specific runaway process of cultural-genetic divergence favoring extreme cultural, and genetic, characteristics.

4. What is the future of human geographic structure?

Modern humans dispersed from Africa into Europe, Asia, and Australia (probably between 60 and 40 Ky ago), colonized the Americas (between 15 and 10 ky ago), and more recently (<3.5 ky) reached remote Oceania. All these events, with few exceptions, put the bases for the establishment of the geographic structure, in populations descended from small numbers of founders and hence highly subjected to random drift.

This process of genetic divergence was counterbalanced by the continuous local gene flow and by major dispersal processes, among which those associated to the agricultural transition (Bellwood, 2004). In different areas of Eurasia and of the Americas, technologies for food production were developed. The resulting increase in the farmers' population size caused dispersal, which favored genetic mixing with previously, settled hunter-gatherer, and the reduction of drift effects. Of course, this process could have also increased the genetic divergence between human groups adopting different subsistence strategies, limiting the levels of gene flow among them. This might have contributed to the genetic isolation of some populations (e.g., Andaman Islanders, Pigmy), but the major effect of farming at global scale was probably the increase of genetic homogeneity (Excoffier and Schneider, 1999).

In very recent times, the level of population structure probably declined even more, because of the continuous but differential increase of the census size (that

produced emigration from countries like Europe in the past or Africa now), the development of transportation means, and more in general the socioeconomical changes. Only in the last few centuries, millions of people from Africa, Europe, and America, relocated in different geographic regions the genomes inherited from their parents, a certain level of mixing with the local genetic pools occurred. In addition, contacts between populations with locally adapted variation for pathogen resistance (such as, e.g., HLA variants) might have produced global selective sweeps, decreasing the population structure also at these genes. Future advances in the biochemical methods to characterize the genes of past populations (e.g., Vernesi *et al*., 2004), and in the statistical methods necessary to analyze complex demographic scenarios (e.g., Beaumont *et al*., 2002; Marjoram *et al*., 2003) will definitely help us to better understand past evolutionary processes leading to the current structuring of the human populations.

If this reconstruction of the evolution of the human population structure is at least approximately accurate, should we simply predict that the "defragmentation" phase that followed the initial "structuring" process would continue? It is hard to imagine what will happen in the future, but a few educated guesses are possible. One is, large numbers of individuals are currently migrating to various areas of the world. However, it is not necessary to assume that large genetic changes will follow. Indeed, most documented historical migration processes that are considered to have contributed to homogenizing genetically human populations, occurred at low population densities. That is the case for all the main dispersal processes leading to the farming expansions, as well as for expansions occurring in the last few centuries. However, at the high densities, typical of modern urban societies, very high numbers of immigrants are necessary to produce significant changes in allele frequencies. In addition, the local effect on population structure will depend not only on the rates of gene flow, but also on the tendency of people to admix, once they are settled in a new region. Examples from the past range from extensive admixture in countries such as Brazil (see e.g., Parra *et al*., 2003) to long-term coexistence of reproductively isolated communities in countries such as India (see e.g., Bamshad *et al*., 2001) or the US (see e.g., Shriver *et al*., 1997), with many intermediate situations. In some cases, a high level of structuring within metropolitan areas is to be expected, with ethnic or linguistic communities living within a few hundred meters of distance showing levels of genetic differentiation comparable to those between subcontinents. Cultural barriers, and not mountain chains or seas, might thus lead to the evolution of a secondary phase of structuring in humans.

Short Specialist Review

Studies of human genetic history using the Y chromosome

Mark A. Jobling
University of Leicester, Leicester, UK

The human Y chromosome's raison d'être is sex (in particular, male sex determination), and this louche connection has made it perhaps the strangest segment of our genome. It is specific to males and constitutively haploid in a diploid organism, and therefore escapes from recombination for most of its length, apart from the two pseudoautosomal regions in which crossing-over with the X chromosome occurs. This absence of intergenerational reshuffling means that it passes from father to son as an immense haplotype, changing only by mutation, and so contains within it a relatively straightforward record of its past. Over the last few years, many useful DNA polymorphisms (*see* Article 68, **Normal DNA sequence variations in humans**, Volume 4) have been discovered in the 23 Mb of nonrecombining euchromatin, and this has led to an explosion in studies of human genetic history using the Y chromosome.

A set of over 200 well-characterized binary polymorphisms representing unique or rare events in human evolution, mostly SNPs (single nucleotide polymorphisms), has been used to define Y-chromosomal haplotypes, known as *haplogroups*. These can be arranged into a unique phylogeny (Figure 1a) rooted by comparison to chimpanzee sequences (Underhill *et al*., 2001; Y Chromosome Consortium, 2002).

The Y chromosome also carries faster mutating markers, in particular microsatellites. These can be used to examine diversity within haplogroups, allowing time to most recent common ancestor (TMRCA) to be estimated, given an estimate of mutation rate (typically ∼0.2% per microsatellite per generation). Intrahaplogroup diversity can be compared between populations, allowing deductions about the geographical origins of population expansions. Typically, most studies analyze a heterogeneous set of 6–20 microsatellites, but recently (Kayser *et al*., 2004), the entire chromosome has been searched for new markers, resulting in the isolation of 172 novel microsatellites to add to the known set of ∼50. This resource should allow new accuracy in the estimation of TMRCAs, and the choice of sets of markers with relatively uniform and predictable mutational properties.

How are Y haplogroups distributed in different populations? The deepest-rooting clades within the Y phylogeny (haplogroups A and B) are almost entirely confined to sub-Saharan Africa (Figure 1b), and one estimate for TMRCA based on SNPs and a model of exponential population growth (Thomson *et al*., 2000) is 59 thousand

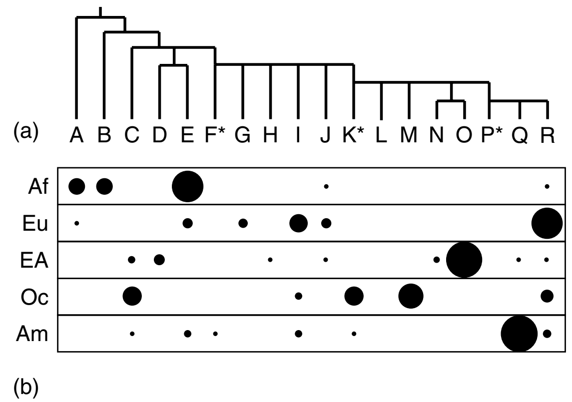

Figure 1 Frequencies of the major Y haplogroups in five continental populations. (a) The Y phylogeny, showing the 18 major haplogroups, A to R. (b) Relative haplogroup frequencies (represented by area of filled circles) in indigenous populations of sub-Saharan Africa (Af), Europe (Eu), East Asia (EA), Oceania (Oc), and the Americas (Am). Data from Underhill *et al*. (2001)

years ago (KYA), with 95% confidence interval limits of 40–140 KYA. These observations are compatible with a recent out-of-Africa origin for modern humans.

The distribution of Y haplogroups shows a generally high degree of geographical differentiation, with, in one study (Seielstad *et al*., 1998), 65% of genetic variance existing between populations, and 35% within. This contrasts starkly with an autosomal figure of 15% between- and 85% within-population variance (Barbujani *et al*., 1997). The difference has been ascribed (Seielstad *et al*., 1998) to the predominant practice of patrilocality, in which women tend to move to the husband's birthplace upon marriage, although this effect may only be appreciable at the local rather than global level (Wilder *et al*., 2004). Another contributory factor is genetic drift: stochastic variation in haplotype frequency from one generation to the next due to variance in offspring number, which is particularly marked on the Y because its effective population size is one-quarter of that of any autosome.

High geographical differentiation makes the Y a powerful system for the study of past population movements, including colonization and admixture. In the case of the Lemba, a Bantu-speaking South African tribe, oral history telling of descent from Jews who came from the north by boat finds support in the fact that they carry a high frequency of a Y-chromosomal haplotype that is typical of Jewish Middle Eastern populations (Thomas *et al*., 2000). Combining Y studies with analysis of maternally inherited mitochondrial DNA (mtDNA; *see* Article 5, **Studies of human genetic history using mtDNA variation**, Volume 1) has revealed evidence for sex-biased admixture, in which men, but not women, from one population have contributed genes to another population. Examples are seen in Greenland, where all mtDNAs analyzed are of Native American origin, while up to 64% of Y chromosomes are European (Bosch *et al*., 2003); and in Brazil, where European Y chromosomes are close to 100% (Carvalho-Silva *et al*., 2001) but mtDNAs originate approximately equally from Europeans, Africans (contributed by imported slaves), and indigenous Native Americans.

High-resolution Y haplotype analysis has revealed the extraordinary extent to which social structures can allow a single individual to contribute disproportionately to future populations (Zerjal *et al*., 2003). About 8% of the Y chromosomes from a large region of CentralAsia (~0.5% of the global total) belong to a very closely related lineage cluster with an estimated TMRCA of only ~1000 years, spread across 16 different populations from the Pacific to the Caspian Sea. The age of the cluster, its distribution, and its probable origin in Mongolia are all consistent with Genghis Khan and his dynasty being responsible for its unprecedented spread.

The discussion above assumes that natural selection is not influencing Y haplotype distributions. Under positive selection, a beneficial mutation could have led to the spread or fixation of a particular Y haplotype in the past. There is no convincing evidence that such a "selective sweep" has occurred, and apparent evidence from diversity data could always be explained as the effect of population expansion (*see* Article 7, **Genetic signatures of natural selection**, Volume 1). Deleterious mutations can occur in essential genes, including those involved in sperm production, but purifying selection acts continually to weed these out; also, the multicopy nature of many spermatogenesis genes may allow correction of mutations through intrachromosomal recombination (gene conversion) with unmutated copies (Rozen *et al*., 2003). Some studies of selection have focused on particular deleterious phenotypes known (or suspected) to be associated with the Y chromosome. Significant effects of Y haplotype on the probability of, for example, having low sperm count (Krausz *et al*., 2001) or prostate cancer (Paracchini *et al*., 2003) have been found, but are likely to have only minor effects on haplotype frequencies in populations. With current knowledge, it therefore seems reasonable to treat haplotype frequencies as an outcome of past population processes. However, advocates of the Y chromosome must not forget that, whatever its allure, it represents but a single "run" of the genealogical process, and that combination with other loci in the genome is necessary to provide a balanced view of the human past from DNA evidence.

Short Specialist Review

Studies of human genetic history using mtDNA variation

Antonio Torroni and Chiara Rengo
University of Pavia, Pavia, Italy

At fertilization, the genetic contribution of the oocyte to the zygote differs from that of the spermatozoon since the latter does not contribute viable mitochondria. These cytoplasmic organelles harbor numerous copies of a circular genome (~16 570 bp), which is characterized by a much higher evolution rate (10–20 folds) than that of the average nuclear gene. Thus, human mitochondrial DNA (mtDNA) is maternally transmitted and its sequence variation, which cannot be reshuffled by recombination as in autosomal genes, has been generated exclusively by the sequential accumulation of new mutations along radiating maternal lineages. Because this process of molecular differentiation is relatively fast and occurred mainly during and after the recent process of human colonization and diffusion into different regions and continents, the different subsets of mtDNA variation tend to be restricted to different geographic areas and population groups.

As a result of these peculiar features, the human mtDNA has a single genealogical history, which can be reconstructed as a gene tree (or network) (Bandelt *et al.*, 1995); migrations (instances of gene flow between regions) can be detected by incorporating the geographical origin of subjects into the tree; and time depth within the tree can be estimated using a molecular clock (Richards and Macaulay, 2001). The application of these principles, now referred to as the *phylogeographic approach* (Avise, 2000) was pioneered in humans by Douglas C. Wallace in the early 1980s.

Before providing some examples of the results obtained in the last 20 years by mtDNA studies, it should be pointed out that, despite its unique features for studying human genetic history, mtDNA remains a *single* locus – prone to genetic drift and possibly under selection – thus, it should not be used as the only tool for inference in human evolution. Conclusions based on mtDNA data require corroboration by other genetic systems (Y chromosome (*see* Article 4, **Studies of human genetic history using the Y chromosome**, Volume 1) and autosomal DNA) and other disciplines (for instance, linguistics, archaeology, and even climatology).

The earliest mtDNA work began by digesting the entire genome with a few restriction enzymes (often five or six) on fairly large sample sets (Johnson *et al.*, 1983). However, this approach attracted public attention only in 1987, when

Rebecca Cann, Mark Stoneking, and Allan Wilson using high-resolution restriction analysis (12 enzymes) obtained a much more detailed mtDNA phylogeny. Their analysis of 147 mtDNAs from the different continents identified what was improperly defined as "the mitochondrial Eve" and led to the hypothesis that all modern mtDNAs descend from a woman who lived in Africa about 200 000 years ago (Cann *et al*., 1987). This proposal generated a fierce debate between the proponents of a recent African origin of anatomically modern humans, and those who favored multiregional alternatives. Although the African root was also supported by the sequencing data from the fast-evolving first and second hypervariable segments (HVS-I and HVS-II) of the mtDNA control region (Vigilant *et al*., 1991), the debate lasted for almost a decade, and was for the most part resolved only when the control region of the first Neanderthal specimen was finally PCR amplified and sequenced (Krings *et al*., 1997), revealing that its sequence fell outside the variation of modern humans and did not contribute to the current mtDNA pool.

During the early 1990s, in parallel with the studies addressing the origin of *Homo sapiens sapiens*, the high-resolution restriction analysis also began to be applied to individual continents on large numbers of samples, with the objective of determining human origins in each major geographic area. This resulted in a much more refined picture of the mtDNA world phylogeny – one in which the haplotype clades, or haplogroups, characterized by one or several diagnostic restriction markers, were usually restricted geographically, some to sub-Saharan Africans, others to Europeans, and yet others to East Asians. Many of these haplogroups could not be distinguished by control-region data alone (despite the popularity of this approach in the 1990s and its wide application in forensics), although they could often be picked out from control-region data after an exploratory combined control-region/restriction analysis (Torroni *et al*., 1993, 1996). The haplogroups could, moreover, be subdivided into smaller evolutionary units by including control-region information (Macaulay *et al*., 1999).

The first large comprehensive population studies were carried out in Native Americans and focused on the origin, timing, and numbers of ancestral migrations from Asia. These revealed that virtually all Native American mtDNAs belonged to haplogroups A, B, C, and D (Torroni *et al*., 1993) – later joined by the uncommon haplogroup X – and that only one or two founder haplotypes for each haplogroup were shared between the Native Americans and their Asian counterparts. This indicated that a limited number of mtDNAs arrived in the Americas, in one or two population expansions from Siberia/Beringia. A conclusion that appears to be entirely supported by the data recently obtained from the analysis of entire mtDNA sequences (Bandelt *et al*., 2003).

In Europe, mtDNA variation was studied for the first time by a number of groups in the early 1990s, mostly focusing on the HVS-I region. Initially, it seemed that the European mtDNA landscape might be so flat as to be almost entirely uninformative with respect to European prehistory suggesting that mtDNA may not be a useful demographic marker system (perhaps due to selection or high rates of female gene flow in recent times). However, high-resolution restriction analysis studies showed that this was not true. Indeed, by supplementing HVS-I data with additional informative variants from the coding region, mtDNA variation

was dissected into these major haplogroups (H, I, J, K, T, U, V, W, and X) (Torroni *et al*., 1996; Macaulay *et al*., 1999), which are now fully supported by the sequence analysis of entire mtDNAs (Finnila *et al*., 2001). The first results from European mtDNA (Richards *et al*., 1998) suggested that only a small minority of lineages dated to the Neolithic, with the remainder dating back to between 15 000 and about 50 000 years ago. The majority appeared to descend from founders of Middle or Late Upper Paleolithic origin. These clades were strikingly starlike, indicating dramatic population expansions, which suggested that they were mainly the result of reexpansions in the Late Glacial or Postglacial period. The results were, however, rather tentative, because they were reliant on comparisons with a very small and inadequate sample from the Near East. However, further work (Richards *et al*., 2000, 2002) showed that, with a sufficiently large sample size and a better resolved phylogeny, clades of mtDNA do indeed exhibit gradients similar to those of other marker systems (Cavalli-Sforza *et al*., 1994), and provided evidence that more than three-fourths of the present-day European mtDNAs could be from indigenous Paleolithic ancestors. This conclusion is supported by some analyses of the paternally transmitted Y chromosome (Semino *et al*., 2000; Rootsi *et al*., 2004), but overall rejected by other studies that infer admixture coefficients considering different potential parental populations (Dupanloup *et al*., 2004). In this debated context, first the molecular dissection of one autochthonous European mtDNA clade (haplogroup V), and much more recently that of haplogroup H – the most common haplogroup in Europe (40–50%) – were particularly informative in revealing that there was indeed a dramatic Late Glacial expansion from the Franco-Cantabrian glacial refuge that repopulated much of the western part of the continent of Paleolithic mtDNAs from about 11 000–15 000 years ago (Achilli *et al*., 2004). To determine whether the refuge area(s) of Eastern Europe played a similar role on the other side of Europe would require, in phylogeographic studies, the identification of similarly informative mtDNA subhaplogroups, and, in admixture studies, the evaluation of Eastern Europe as a potential homeland for a parental population.

After having passed through a number of technological and methodological stages, the analysis of mtDNA variation is now in the era of complete mtDNA sequences, and this has opened new, interesting perspectives. This procedure is allowing the identification of new subhaplogroup markers that can be very informative also at the microgeographical level. In addition, the phylogeny of complete sequences has shown that some internal clades are disproportionately derived, compared with others – a result not consistent with a simple model of neutral evolution with a uniform molecular clock – hinting at a role for selection in the evolution of human mtDNA (Torroni *et al*., 2001). This notion has been further developed by Ruiz-Pesini *et al*. (2004) who proposed that the relative frequency and amino acid conservation of internal branch replacement mutations has increased from tropical Africa to temperate Europe and Siberia, and the same haplogroups correlate with increased propensity for energy deficiency diseases as well as longevity. Thus, specific mtDNA replacement mutations permitted our

ancestors to adapt to more northern climates, and these same variants influence our health today.

Short Specialist Review

The genetic structure of human pathogens

Daniel J. Wilson and Daniel Falush
University of Oxford, Oxford, UK

The contemporary genetic structure and the evolutionary history of human pathogens are important to control and prevention strategies, as well as providing interesting case studies in evolutionary biology. Recently, large-scale DNA sequence data have become available for a wide variety of pathogens, and have revealed a variety of structures as diverse as the pathogens themselves. We describe the patterns observed in several of the most notorious killers, and ask what makes them so different from each other.

The genetic structuring that a human pathogen exhibits not only varies from species to species but also from one place to another. A good example is the protozoan parasite *Plasmodium falciparum*, responsible for the most virulent form of human malaria. *Plasmodium falciparum* populations exhibit a wide range of genetic structures that highlight the importance of local epidemiology. Unlike many human pathogens (viruses and bacteria in particular), *P. falciparum* has an obligate sexual stage in its life cycle. Male and female gametes fuse in the mosquito vector to form a short-lived diploid stage. In general, recombination breaks down associations between particular alleles at different loci (linkage disequilibrium). Nevertheless, strong linkage disequilibrium caused by inbreeding is typical in areas of low prevalence where self-fertilization is commonplace, such as South America. In contrast, *P. falciparum* populations in Africa exhibit high heterozygosity and low linkage disequilibrium, more typical of breeding populations, while populations in Southeast Asia show intermediate levels (Anderson *et al*., 2000).

Genetic structuring can persist stably in a pathogen population in spite of transient epidemic waves, a pattern that is seen in *Neisseria meningitidis*. These waves can often be attributed to the transmission of specific genotypes (Zhu *et al*., 2001). The agent of meningococcal meningitis and septicemia, *N. meningitidis*, is a common, diverse bacterium (Jolley *et al*., 2000), which undergoes recombination at a rate sufficiently high to render the phylogenetic signal between loci incongruent (Holmes *et al*., 1999). Zhu *et al*. (2001) showed how the importation of gene fragments from other *Neisseria* species – which might actually be more frequent than within-species recombination (Linz *et al*., 2000) – can drive these waves. Since the 1960s, subgroup III *N. meningitidis* has caused three successive waves of meningococcal disease worldwide. Within each wave, interspecific recombination

can lead to escape variants with novel antigenic properties. They enjoy transient superiority and rise in frequency, but do not subsequently persist because they do not successfully colonize new host populations. So, although immunological novelty is an important advantage, stabilizing selection may account for the persistence of lineages over time.

Not just recent epidemic waves but the origin and subsequent spread of the entire species may be recorded in the population structure of a recently evolved pathogen. One such historically important pathogen is *Yersinia pestis*, the highly virulent bacterium responsible for plague. The first recorded plague pandemic dates to 541–767 A.D., and is thought to have been imported from East or Central Africa and spread from Egypt to Mediterranean countries. Its extremely limited nucleotide sequence diversity makes genetic analysis difficult because of the lack of polymorphism. A study by Achtman *et al*. (1999) using restriction fragment length polymorphisms revealed that *Y. pestis* is a highly uniform clone of *Y. pseudotuberculosis*, a global pathogen of wild and domestic animals, which infrequently causes a self-limiting infection in humans. On the basis of a comparison of the genome sequences of *Y. pestis* and *Y. pseudotuberculosis*, Prentice *et al*. (2001) have postulated that the critical event in the emergence of *Y. pestis* was the acquisition of a plasmid conferring pathogenicity by horizontal gene transfer. Achtman *et al*. (1999) fitted a model of rapid population expansion to date the origin of the pathogen at 1500–20 000 years ago, consistent with the date of the first pandemic.

It is somewhat counterintuitive to think that a microbe as strictly clonal as *Y. pestis* might have originated from a recombination event in which it acquired a pathogenicity-conferring plasmid. The emergence of the apparently nonrecombining (McVean *et al*., 2002) hepatitis C virus (HCV) in Egypt has been attributed to human medical intervention. HCV, in contrast to *Y. pestis*, exhibits high levels of sequence diversity despite its clonal nature. A leading cause of liver cancer and cirrhosis, HCV is genetically structured into various subtypes, of which 4a is prevalent in Egypt. Pybus *et al*. (2003) performed statistical analysis of the genetic structure within subtype 4a. Their coalescent approach was based on an epidemiological model that dated the period of expansion of subtype 4a to between 1930 and 1955, coinciding with an extensive anti-schistosomiasis vaccination campaign in the country. Moreover, the high rate of spread estimated by the analysis is consistent with existing hypotheses that implied spread by unsterile equipment.

There have been attempts to extract information about historic changes in prevalence even from highly recombining pathogens, the epitome of which must be the human immunodeficiency virus (HIV), which, according to population genetic estimates, is perhaps the most highly recombining of all microorganisms (McVean *et al*., 2002). Lemey *et al*. (2003) fitted a similar model to that of Pybus *et al*. (2003) to HIV-2 gene sequences obtained from patients in Guinea-Bissau. They found that the transmission of HIV-2 increased around 1955–1970, overlapping with the 1963–1974 war of independence in the country. Their analysis hints at the role of social changes, such as wartime, in the establishment of emergent infections.

If the driving force in the historic spread and subsequent globalization of a pathogen was the migration of its host populations, then a pathogen's contemporary genetic structure can contain information about its host past, as has been seen

in *Helicobacter pylori*, a common bacterium that colonizes the human gut and, through a process of constant irritation, is apparently responsible for most of the stomach maladies found in man, including peptic ulcer and gastric cancer. Recombination in *H. pylori* is so high that different loci, and polymorphisms within loci, appear to be in linkage equilibrium (Suerbaum *et al*., 1998), the result of very frequent recombination during mixed colonization by unrelated strains (Falush *et al*., 2001). Nevertheless, Falush *et al*. (2003) found that contemporary *H. pylori* could be divided into seven populations with distinct geographical distributions. The high sequence diversity and residual linkage disequilibrium in modern populations allowed the identification of ancestral populations from Africa, Central Africa, and East Asia. By reconstructing the genetic profiles of these ancient populations, they were able to produce putative migration routes for the ancient populations, migration routes that parallel hypothesized ancient human migration routes. Thus, analysis of *H. pylori* from human populations appears to provide independent insight into the details of human migrations.

The exceptional population structure of *H. pylori* allows reconstruction of the host evolutionary history, highlighting the intimate association of the host and parasite over thousands of years. But why does diversity within *H. pylori* correlate so well with human migrations, when others do not?

In fact, a lack of correlation is generally much easier to explain than a good correlation. Both HIV and *N. meningitidis* spread epidemically, with a transmission time measured in weeks or years rather than decades. Although geographical and cultural barriers can slow down their spread, current levels of human movement have proved sufficient to allow their global dissemination within years or decades. *Mycobacterium tuberculosis*, the cause of TB and human suffering that has inspired many literary works, spreads more slowly, and does show clear patterns of geographic structuring (Hirsh *et al*., 2004). However, because TB is apparently entirely clonal (Supply *et al*., 2003), any selective events associated with the adaption of TB to the human host, or host-pathogen coevolution, will affect the population structure across the entire genome, an example of which may be the global emergence of the hypervirulent Bejing genotype (Lillebaek *et al*., 2003).

The population structure of *H. pylori* is exceptional because its biology includes several key properties. These include slow transmission (which typically seems to occur in families), and, in the absence of antibiotics, typically life-long chronic infection. Further, it mutates at very high rates, which results in informative signals at each gene, while frequent recombination uncouples the signal observed at most genes from selective events that occur at antigenically important loci. Are there other pathogens with a similar suite of properties? Despite a few candidates (e.g., JC virus, Agostini *et al*., 1997), none really seems to fit the bill, but only time will tell which of our unwanted but intimate companions has most to reveal about our own history.

Short Specialist Review

Genetic signatures of natural selection

Molly Przeworski
Brown University, Providence, RI, USA

Carlos D. Bustamante
Cornell University, Ithaca, NY, USA

1. Introduction

Identifying genomic regions involved in the adaptive divergence of closely related species or populations is a major goal of evolutionary genetics research. Adaptations come about through a variety of modes, including global selection for a particular allele, local adaptation, where alternative alleles are favored in different environments, and balancing selection (heterozygote advantage), where increased diversity is favored at a particular locus. These modes of selection make distinct predictions regarding the distribution of inter- and intraspecific genetic variation near the selected region, thus leaving a distinguishing "signature". For example, repeated favorable changes to a protein lead to accelerated rates of amino acid evolution between species relative to synonymous substitution rates, while long-term heterozygote advantage increases intraspecies diversity around the selected site (Hudson and Kaplan 1988).

2. Using interspecies divergence

Over the past three decades, mathematical and computer models have helped to characterize the signature of natural selection on nucleotide sequence variation (e.g., Maynard Smith and Haigh 1974; Hudson and Kaplan 1988; Takahata 1990). On the basis of these characterizations, statistical approaches have been developed to identify genomic targets of adaptation and make inferences about current and past selective pressures. An important class of methods aims to detect nonneutral evolution of amino acid sequences using phylogenetic patterns of synonymous and nonsynonymous variation (for a review, see Yang and Bielawski 2000). These approaches have been successful in identifying a subset of proteins with an accelerated rate of amino acid evolution (e.g., Clark *et al*., 2003), but cannot

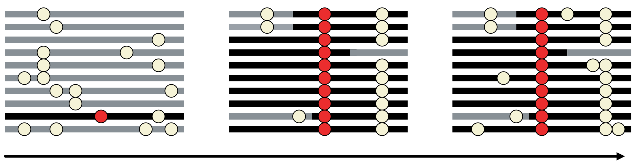

Figure 1 The effect of a "selective sweep" on linked neutral variability. Each line represents a chromosome and the circles the nonancestral allele at a site. Light yellow circles are mutations with no fitness effect, i.e., which evolve neutrally. A favorable mutation arises (shown in red) and, because it is favored, increases rapidly in frequency in the population. It recombines onto a limited number of haplotypes during its ascent; how much recombination occurs depends on the recombination rate and the strength of selection. After fixation, variability is replenished by mutation. However, for a while, most mutations are new and therefore tend to be at low frequency

detect adaptations consisting of few substitutions to a given protein or changes that occur outside of the coding region.

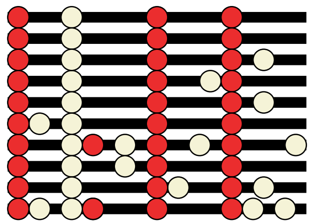
3. Using polymorphism data

Regulatory adaptations or subtle adaptations in proteins may be detectable from patterns of polymorphism in samples of extant individuals, so long as the selective events are recent. Indeed, when a rare allele arises and rapidly fixes in the population, it distorts patterns of variation at linked neutral sites relative to the expectation in the absence of natural selection (Maynard Smith and Haigh 1974) (see Figure 1). Under simplifying assumptions, this signature of a "selective sweep" can be exploited to find regions that have been the target of positive selection in the past $\sim N_e$ generations, where N_e is the diploid "effective population size" of the species (Przeworski 2002). In humans, estimates of N_e are on the order of 10 000, suggesting that polymorphism-based approaches can be informative about selective events over the past ∼250 000 years, including those associated with the emergence of anatomically modern humans.

The most common methods used to identify adaptive genetic changes from polymorphism data are the so-called tests of neutrality. These tests begin by assuming a neutral null model of a random-mating population of constant size (the "standard neutral model") and then assess whether the value of some summary of the data (e.g., the number of segregating sites) is unexpected under this model. A poor fit of the standard neutral model is interpreted as evidence for the action of natural selection. Commonly used test statistics are summaries of the allele frequencies (e.g., Tajima 1989) or of linkage disequilibrium (e.g., Hudson *et al*., 1994). The power of these tests varies widely (e.g., Simonsen *et al*., 1995).

Although tests of neutrality have been used extensively to identify genes that may have experienced recent adaptations, they suffer from a number of drawbacks. For one, there is no obvious way to combine tests performed on different but correlated aspects of the data. In addition, the approach does not allow one to estimate the parameters of interest, such as the timing of the selective event or the strength of selection. Moreover, while a significant result suggests that the data are unlikely

under the null hypothesis, it says nothing about whether the data are more likely under a model of natural selection.



Some of these shortcomings can be addressed by the use of likelihood-based methods that explicitly compare the probability of the data under a model with selection versus without and allow one to estimate parameters (Kim and Stephan 2002; Przeworski 2003). At present, it is not computationally feasible to make these inferences using all the polymorphism data, even for simpler models. Instead, these methods base themselves on (multiple) summaries of the data that are known to be sensitive to selection at a linked site. Although the methods sacrifice some of the information carried by polymorphism data, they have been shown to produce reliable results on data simulated under standard assumptions.

What is less clear is how these methods perform on data generated under more realistic models. Like tests of neutrality, they rely on highly simplified assumptions about the population history. Since allele frequencies are known to be sensitive to demographic assumptions (e.g., Tajima 1989; Simonsen *et al*., 1995), as are other aspects of the data, methods based on these may not be reliable when applied to real data. In particular, when some of these statistics are used as tests of neutrality, they have high rates of Type I error (probability of rejecting a true null hypothesis) if unknown population structure is present (Nielsen 2001; Przeworski 2002). Thus, the interpretation of significant results is not straightforward. In that respect, a potential benefit of using multiple aspects of the data (or all the data) is that the method may be more robust to the misspecification of the model.

Ideally, of course, one would like to incorporate more realistic features of the demographic history. Unfortunately, little is known about appropriate demographic models for species of interest. As an illustration, although the human population has obviously increased in size, we currently have little idea of when or where population growth occurred. An alternative would be to allow for a model of demography and selection and coestimate all demographic and selective parameters. At present, however, this is not computationally feasible. When the aim is to detect selective pressures acting on a particular class of mutations (e.g., amino acid replacements), a third approach is to employ statistical tests that do not rely on an explicit population genetic model but rather look for discordance between distinct functional classes of sites. For example, Akashi (1997) proposed comparing the distribution of allele frequencies at preferred and unpreferred codons as a test of neutrality, and the same can be done for silent versus replacement sites. If a subset of sites are invariant, while the remaining silent and replacement sites are evolving neutrally, the proportion of variable sites that are silent versus replacement should be the same across all frequency ranges – irrespective of the underlying demography of the species. This neutral expectation can be evaluated by a simple goodness of fit test (by conditioning on the total number of polymorphic sites in a set of nonoverlapping frequency ranges).

4. Combining polymorphism and divergence data

In the same spirit, levels of variation within and between species can be compared for silent versus amino acid replacement changes (e.g., McDonald and Kreitman

	Polymorphism	divergence
Amino acid replacement	1	3
Silent replacement	9	1

Figure 2 Effect of repeated beneficial changes in a protein.
Amino acid changes are shown in red and silent changes in yellow. The data in the sample are summarized in the McDonald–Kreitman table shown to the right. Alleles carried by every chromosome in the sample are assumed to be fixed in the species. If mutations at synonymous sites are neutral, a larger ratio of amino acid to silent fixations relative to amino acid to silent polymorphisms suggests that the protein is evolving under positive selection (in this example, P = 0.041, as assessed by a Fischer's Exact Test)

1991). The McDonald–Kreitman (MK; described in Figure 2) and Akashi tests are fully robust to demography since they depend only on differences in patterns of variation among classes of sites that share the same evolutionary histories, that is, no demographic assumptions need to be specified to test the null hypothesis of neutrality of mutations. In their current formulation, MK and Akashi tests are inapplicable to changes that occur outside of the coding region. In principle, similar methodology could be extended to noncoding regions; however, the utility of the approach will depend on the ability to accurately dichotomize noncoding sites as functional or nonfunctional.

MK data can also be used to infer the magnitude and directionality of natural selection if one is willing to specify a demographic model and a selective alternative to neutrality, such as genic selection (Sawyer and Hartl 1992). An advantage of such a model-based approach is that one can directly compare the inferred strength of selection across genes and classify loci into those that show evidence of being subject to deleterious mutations, neutrally evolving, or putatively positively selected. The parameterized test of neutrality has the same Type I error and power as the usual MK table (described in Figure 2). In contrast to significance testing, however, parameter estimation does depend on the specifics of demography and recombination used to estimate the strength, and possibly the directionality, of selection. One way to increase the reliability of these model-based approaches may be to combine genomic patterns of polymorphism and divergence for different classes of sites *across the genome* in order to detect selection in a given gene. Such an approach has been shown to increase power while maintaining a relatively high robustness to the misspecification of the null model (Bustamante *et al*., 2002).

5. Empirical approaches

The last few years have also seen the use of observed distributions of human genetic variation to identify loci under selection. To date, researchers have taken

one of two approaches: in the first, they have contrasted a set of candidate loci to putatively neutrally evolving regions in an attempt to "control" for genome-wide demographic effects (e.g., Gilad *et al*., 2003). In the second, they have ranked loci according to some summary of the data and focused on the subset in the tails of the empirical distribution (e.g., Akey *et al*., 2002). These empirical approaches circumvent some of the difficulties involved in specifying a demographic model but at a cost, since little can be learned about a region once it has been identified as unusual. Moreover, although these approaches do not rely on a model, they make a number of implicit assumptions: in particular, the second approach is only practical if most loci in the tails of the distribution are indeed targets of selection. Whether this condition is likely to be met depends on the nature and strength of selection as well as on the demographic parameters (cf. Beaumont and Balding 2004).

6. Ascertainment bias

A final caveat pertains to ascertainment bias in population genetic data. Almost all of population genetic theory for detecting natural selection assumes that the researcher has full sequence for all individuals in the sample. Yet, there is growing popularity of schemes where one uses a small "discovery" panel to identify common SNPs (single nucleotide polymorphisms) and then types these markers in a much larger sample to obtain gene frequency estimates across populations. These schemes violate the assumptions of the methods, leading to invalid analyses unless the ascertainment process is explicitly and accurately modeled (cf. Nielsen and Signorovitch 2003). This is particularly problematic for population genetic analyses based on pooling ascertained data (such as that found in large public databases e.g., dbSNPs). Such analyses run the risk of detecting patterns that do not result from natural selection but instead from inherent biases in the data.

7. What have we learned thus far?

Recent analyses of genomic patterns of variation have helped to discern the principal modes of adaptation. Notably, the use of MK tables (and related approaches) has suggested that many coding region mutations are weakly deleterious, such that they can persist as polymorphisms in the population but rarely contribute to divergence (e.g., Akashi 1995; Weinreich and Rand 2000; Hellmann *et al*., 2003). Similar approaches also indicate that most amino acid changes fixed between *Drosophila melanogaster* and *Drosophila simulans* are adaptive (e.g., Sawyer *et al*., 2003).

In addition, surveys of noncoding variation in *D. melanogaster* and other species have revealed decreased polymorphism, but not decreased divergence, in regions of low recombination (Begun and Aquadro 1992). This observation has no clear neutral explanation and is likely due to repeated episodes of directional selection at linked sites (Andolfatto and Przeworski 2001). From these lines of inquiry, it is apparent that natural selection shapes the patterns of genetic variation; the challenge is to harness this signature to help identify specific regions that underlie adaptations.

We already have a number of convincing examples: balancing selection at Adh in *D. melanogaster* (McDonald and Kreitman 1991) and the MHC complex in mammals (Hughes and Nei 1988), or repeated directional selection on reproductive proteins in mammals (e.g., Swanson *et al*., 2001) and on the HIV envelope gene (Nielsen and Yang 1998). What strengthens the interpretation in these cases is that the finding makes biological sense in light of the phenotype. When such independent knowledge is not available, statistical methods are only a starting point for further functional analyses. As an illustration, both polymorphism and divergence data strongly suggest that directional selection has shaped the evolution of *FOXP2*, a gene involved in speech and language in humans (Enard *et al*., 2002). However, to substantiate this hypothesis, we need a better understanding of the function of *FOXP2*.

8. Outlook

The current wave of comparative evolutionary genomics promises to identify many loci that show evidence of positive selection based on patterns of DNA sequence variation. While these approaches will generate a number of interesting hypotheses, it is important to realize that they are not ends in themselves and that the ultimate utility of this research program depends on experimental confirmation. We therefore look forward to efforts to verify (or disprove) these hypotheses via comparative functional analysis of molecular, cellular, and organismal phenotypes linked to putatively adaptive genotypic variation.

The role of gene regulation in evolution

Matthew V. Rockman
Duke University, Durham, NC, USA

Evolutionary biologists have long sought to understand the genetic basis of evolutionary change. For theoretical reasons, biologists have predicted that mutations affecting the regulation of gene expression, rather than the physical structure of gene products, will play a central role in phenotypic evolution. Recent empirical work has begun to nail down the molecular details underpinning phenotypic evolution, and in a remarkable number of cases, the evidence strongly supports the theoretical models.

Two disparate schools of theory have predicted the central role for gene regulation in evolutionary change. The critical parameter for both accounts is pleiotropy, the phenomenon whereby a single mutation has multiple phenotypic effects.

One school of thought, growing out of mathematical population genetics and quantitative genetics, holds that mutations fixed by evolution are likely to be those with very limited pleiotropic effects (Fisher, 1930). Because extant organisms must be in some sense fit for survival, a mutation that alters many features at once is likely to change at least some of them for the worse. A mutation that alters only a single feature stands a better chance of improving the organism's prospects, and therefore spreading through the populations.

Regulatory mutations, particularly those that affect transcriptional regulation, are ideal candidates for mutations with restricted pleiotropy. The temporal and spatial pattern of a gene's expression, the quantitative profile of its transcription rate, and its responsiveness to a range of inductive cues are influenced by the binding of transcription factors to cis-regulatory DNA elements. Because the array of transcription factors differs among cells, each piece of the total expression pattern may be regulated independently by a unique complement of transcription factors and a discrete segment of regulatory DNA (Arnone and Davidson, 1997). Cis-regulatory mutations that affect expression in one part of the organism may leave expression in other parts unchanged. This modular property of transcriptional regulation makes cis-regulatory DNA conducive to evolutionarily important mutation (Gerhart and Kirschner, 1997; Davidson, 2001).

A second school of thought, growing out of evolutionary developmental biology and molecular evolution, holds that the mutations responsible for the conspicuous phenotypic transformations that account for the diversity of organismal form are

likely to be those with quite radical pleiotropic effects. More specifically, a mutation with coordinated pleiotropic effects, radically altering form in a coherent and systemic fashion, is a mutation that could account for a dramatic change in form while retaining functional integration.

While evolutionary change affecting a suite of integrated traits could be due to a large number of separate mutations, a single mutation influencing the whole suite of traits is more likely to preserve functional integration, particularly when the traits are genetically correlated by a shared developmental basis. Even before the molecular mechanisms of development were well understood, this notion found footing in the concept of heterochrony (e.g., Gould, 1977), whereby simple changes in the timing of developmental events resulted in dramatic, but functionally integrated, changes in form. Of course, heterochronic changes in timing are likely to result from changes in the temporal or quantitative regulation of gene expression. The argument for coordinated pleiotropy is famously realized in King and Wilson's (1975) model for human origins. Because humans and chimpanzees are so similar at the level of structural genes, they argued, the striking phenotypic differences between the species must be due to a small number of mutations with systemic effects.

At the same time, developmental biologists have found that the set of genes regulating development is largely shared among animals (and similarly among plants), a finding confirmed by the proliferation of whole-genome sequences and EST projects. Given a shared "toolkit" of developmentally important proteins, evolutionary developmental biologists have embraced the notion that changes in form are due to changes in the pattern of expression of the shared genes, and the recruitment of whole developmental networks to evolutionarily novel tasks (e.g., Lowe and Wray, 1997). Studies correlating changes in patterns of gene expression to changes in phenotypic form have become a mainstay of evolutionary developmental biology.

The theoretical commitments to limited pleiotropy on the one hand, and to pervasive, integrated pleiotropy on the other hand, have been brought together and reinforced by recent empirical work, which bridges the divide between the developmental biologists, who have focused on comparisons among species, and quantitative geneticists, who have been examining variation within species. Although case studies documenting the role of regulatory mutations in the genetic basis of phenotypic evolution are now numerous (e.g., Sucena *et al*., 2003; Beldade *et al*., 2002; Wang and Chamberlin, 2004; Wang *et al*., 1999; Enattah *et al*., 2002), an extraordinary recent study of stickleback fish (*Gasterosteus aculeatus*) exemplifies the role of gene regulation in meeting the competing needs of limited pleiotropy and systemic effects.

Shapiro *et al*. (2004) genetically mapped the loci underlying the dramatic and very recent evolutionary reduction of the pelvic skeleton in lake populations of sticklebacks. A virtue of this study is that the mapping strategy makes no a priori assumption about the cis-regulatory nature of the underlying locus. Shapiro *et al*. found that a single major locus accounts for a suite of pelvic traits, consistent with the coordinated pleiotropy model. The locus was identified as *Pitx1*, a transcription factor, but no differences were seen in the protein sequence. Instead, the fish with and without pelvic skeletons differ in the spatial pattern of *Pitx1* expression during development. Fish with reduced skeletons show a loss of expression at the site

of the presumptive pelvic region. At the same time, expression of the gene in a variety of other developing organs is retained, consistent with the restricted pleiotropy model. Because the complete knockout of *Pitx1* (in mice) is lethal, the evolutionary importance of the spatially limited mutational effect can hardly be doubted.

Regulatory mutations fit the theoretical bill for evolutionarily important mutations. But phenotypic evolution certainly involves mutations of all sorts – indeed, recent work revealing the extent of positive selection on amino acid substitution in human evolution (Clark *et al*., 2003) shows that structural mutations are essential contributors to the origin of our own species, despite the predictions of King and Wilson (1975). If regulatory mutations are rare, then their importance to evolution, regardless of their suitability, may be minimal. Three recent findings suggest that regulatory mutations may actually constitute the majority of phenotypically relevant variation in populations. First, comparative genomics has revealed that a surprising fraction of noncoding DNA is conserved among divergent species (e.g., Rat Genome Sequencing Project Consortium, 2004). Because evolutionary conservation implies functional importance, it seems that most of the functional nucleotides (in mammalian genomes, at least) are noncoding and potentially cis-regulatory. These nucleotides, therefore, represent a bigger target for mutation than do coding sequences. Second, surveys of noncoding variants (again, in humans) suggest that a large fraction affect transcription (Rockman and Wray, 2002; Buckland *et al*., 2004). Because we lack a means to infer the functional import of cis-regulatory DNA directly from sequence, however, our understanding of the extent of regulatory variation remains limited. Third, genome-wide analyses of gene expression variation in a range of species have shown that such phenotypic variation is ubiquitous (e.g. Jin *et al*., 2001; Cavalieri *et al*., 2000). Although efforts to map the loci responsible for the variation are highly sensitive to experimental design and statistical analysis issues, one of the best studies to date found that the majority of such loci map to the same genetic location as the variable transcript, implying that the loci may be cis-acting (e.g., Brem *et al*., 2002). Allele-specific measurement of gene expression, a technique that exclusively discovers the effects of cis-acting variation, also reveals the presence of abundant variation in humans (Lo *et al*., 2003). Consequently, putting aside all theoretical commitments, we should not be surprised to find regulatory variation underlying phenotypic variation.

Empirical and theoretical results point to changes in gene regulation as a major factor in phenotypic evolution. As molecular quantitative genetics continues to make strides in connecting phenotype and genotype, our understanding of the molecular basis for evolutionary change will grow even richer.

Short Specialist Review

Modeling protein evolution

David D. Pollock
Louisiana State University, Baton Rouge, LA, USA

Richard A. Goldstein
National Institute for Medical Research, London, UK

Proteins are the biological macromolecular entities most closely and directly related to organismal function, and knowledge of protein structure and function is critical to understanding biological organization. The evolution of protein sequence is molded by the specific requirements of structure and function, and thus an important avenue for predicting features of protein structure and function is to model the evolutionary process in proteins. Despite this, models of protein evolution have lagged far behind models of DNA evolution. An obvious and important reason for this is that proteins are composed of 20 amino acids, while DNA is composed of only four nucleotides; it is both harder to make calculations with amino acids and harder to find data sets sufficiently large to accurately estimate substitution probabilities between so many states. These problems become compounded when the evolutionary process occurring at the DNA and protein levels are combined to model evolution of amino acid coding units (codons, which have 64 states). A somewhat more subtle point is that DNA models have progressed partly because they usually assume, implicitly or explicitly, that nucleotide substitutions during the course of evolution occur in a random, or neutral fashion, with all positions at all times evolving independently in the same manner and rate. In contrast, experimental evidence (e.g., mutagenesis and functional analysis) has long shown that different positions in proteins can have wildly different tolerances for different amino acids and that nonadditive or interactive functional relationships among positions abound.

Although it causes computational difficulties, the complexity of protein evolution also provides useful opportunities. Because proteins are under higher degrees of selective pressure, they often change more slowly, and their evolution can allow us to look back further in evolutionary time. The dependence of the evolutionary process on a protein's structure and function means that we can use the evolutionary data to gain insight and understanding of these fundamental characteristics. Studying changes in the evolutionary process of individual proteins can tell us about how protein structure and function change over time. Finally, the sequence databases represent the record of eons of natural mutagenesis and selection experiments, allowing us to probe the relationship between protein sequence and resultant protein properties.

A number of recent developments have allowed the modeling of protein evolution to become a more accurate, diversified, and broadly useful pursuit. An increase in computational power is perhaps foremost among these developments, but not simply because the same old calculations can be performed faster. In addition to increasing speed, computational advances have spurred and made practical the development of novel and sophisticated statistical methodologies using complex models that were unthinkable when computers were slower. These fundamentally model-based approaches allow incorporation of biochemical knowledge and testing of evolutionary hypotheses in a flexible and statistically sound manner. They also allow the incorporation of hypotheses concerning the phylogenetic relationships among genes or species, a component that is essential for reducing noise and spurious correlations in evolutionary analyses. The simple but obviously incorrect assumption of treating sequences as though they are independent (unrelated) entities is no longer necessary or advisable.

Another important development, the same that spurred the creation of the genomics and bioinformatics fields, was the advent of rapid, cheap, and large-scale DNA sequencing capabilities. Along with the sequencing efforts focused on obtaining large quantities of sequence from one or a few species (which except for large multigene families are relatively useless for studying evolutionary processes), there has also been considerable production of homologous sequences from divergent organisms. This sampling of many taxa, or "genomic biodiversity", is essential to the development of sophisticated and realistic models of protein evolution, since discerning the evolutionary behavior at individual sites requires enough biodiversity data such that many substitutions will have occurred at each individual site over the evolutionary time during which the sequences diverged.

Finally, the newest and potentially most revolutionary developments have been in the fields of protein structure prediction, experimental determination, and design. Despite a tradition of unbridled optimism, protein folding and structure prediction has long been problematical and even less tractable than studying protein evolutionary dynamics. There has been more success with the inverse problem, that of finding sequences that conform to a particular fold. A dramatic recent success in the inverse folding field used a heuristically optimized combination of simple energy potentials and observed distributions of conformations for both amino acid side chains and main chain oligomers. Calculations for these methods are relatively rapid, and are in the range of being useful for evolutionary studies and predictions. In addition, observations of adjacency statistics between pairs of residues in an enlarged database of three-dimensional protein structures (from X-ray crystallography or NMR), although obviously crude, have provided useful information for modifying amino acid substitution probabilities, and have provided semirealistic complex models for simulating long-term evolutionary processes and discovering consequences of these processes that may be reflected in real proteins.

How then have models of protein evolution been developed to incorporate biological realism? For a long time, substitution models were never inferred from an individual data set of interest, but were instead obtained from observations of differences between many closely related protein pairs or sets of sequences. Since these observations were averaged over protein positions, evolutionary time, and many unrelated proteins, they necessarily assumed an unwarranted consistency.

Relatively early modifications included specific focus on slowly evolving sites, particular genome types (e.g., mitochondria or viral genomes), or residues involved in particular structural features (e.g., α-helices, β-sheets, or buried residues and residues exposed to solvent), as well as collecting observations for different amounts of evolutionary divergence. Eventually, models of transition between these different contexts along the sequence (hidden Markov models) were used to allow incorporation of these specialized observations into phylogenetic likelihood analysis. Some success in predicting secondary structure was achieved, along with more probable reconstructions of protein phylogenies. Still, though, there was not great reason to believe that these specialized contexts, defined on the basis of preconceived conceptions of what might be most important in determining evolutionary processes, did not represent unknown amalgams of heterogeneous processes that were yet to be deciphered. Although incorporation of rate variation among sites, a technique used in DNA evolutionary analysis, was used to address some of this hidden variation, an important advance was the use of mixture models and substitution matrices derived as functions of the chemical properties of amino acids. These mixture models allow the associations of substitution matrices with positions in an alignment to arise freely during the course of analysis, and thus can obtain novel information and produce inferences that are not possible when the substitution classes are predefined. The evolutionary process may also change over time, but evolutionary models incorporating such change are still in their infancy, and still limited by the size of current data sets.

One of the more important reasons for improving models of evolution in proteins is to understand the forces of selection that act on proteins, and to separate these forces from stochastic processes that affect substitution probabilities (random drift). Although it cannot be said that these two processes of change have been cleanly separated, in many cases statistical features have been evaluated that strongly indicate selection. The most clear-cut cases are those of diversifying selection, in which a sort of molecular cat-and-mouse scenario emerges that drives amino acid substitution at an accelerated rate that is greater than neutral expectations. Such scenarios may occur commonly in situations involving, for instance, a pathogen avoiding a host immune response, but still represent special cases and are not observed in most proteins. It is much more common that a burst of amino acid substitution might occur on a particular branch, possibly as a result of a change of function or specificity, and this may be detected as a brief elevated rate of amino acid versus nucleotide substitution. It is also possible to detect coevolution between residues in proteins, in which case substitutions at one position alter substitution probabilities at other positions. When genes have duplicated, it is possible to detect changes in rates or patterns of substitutions at individual sites, and thus to identify changes that may have been due to functional divergence. Finally, it is possible to use evolutionary analysis to predict ancestral sequences; these can then be resurrected and analyzed to infer patterns of functional change along the phylogeny (a process sometimes referred to as "paleobiochemistry").

Despite the successes of these types of analyses, it may still be argued that we are far from a complete and realistic model of protein evolution. Many of the techniques used simply detect extreme evolutionary processes or unexplained changes in the evolutionary process, while the causal mechanism (adaptive burst,

functional divergence, coevolution) is more a matter of perspective and hope than of direct evidence. Many of these mechanisms may be related and interact in ways that have yet to be deciphered. Evolutionary analyses have also not yet made dramatic progress in prediction of protein structure and function, although preliminary results are promising. The advances in protein engineering are therefore quite exciting, in that they may provide an avenue for integrating models of evolutionary change with realistic biophysical models that predict sequence compatibility with specific structures. Simple pairwise contact probabilities have already been used to model sequence evolution in structures from the protein data bank, and the full integration of structure and function prediction methods with models of protein sequence evolution may soon provide more accurate and useful tools for both purposes.

Measuring variation in natural populations: a primer

Henry Harpending
University of Utah, Salt Lake City, UT, USA

1. Sources of data

Most measures of variation (synonymous with diversity) in natural populations quantify the average amount of difference between two entities from a defined population. For example, biologists may be interested in differences in size or length among organisms in a population, differences among DNA or protein sequences from those organisms, and so on.

Variation in quantitative traits (synonymous with metric traits) such as mass, length, or color is quantified with standard statistics such as means, variances, and covariances. Many work with the logarithms of measurements rather than with the measurements themselves. The statistics have useful properties when the measured quantities are normally distributed, and the distributions of logarithms of metric traits are often more like normal distributions.

Classical markers are polymorphisms where DNA variation is detected indirectly rather than by sequencing. The first to be studied systematically were immunological markers such as the ABO and Rh loci. At the ABO locus, for example, a chromosome could code for A-substance, B-substance, or no substance. Over time, technologies appeared that increased the number of markers: electrophoresis allowed protein variants to be distinguished, and restriction enzymes that recognize and cut a specific short nucleotide sequence led to a large number of markers for restriction fragment length polymorphisms (RFLPs) where the alleles were either cut or not cut by a specific enzyme. Methods of measuring diversity for all these are essentially the same, computation of expected heterozygosity under random mating. As large-scale sequencing of DNA has become feasible, these classical markers have fallen into disuse.

Classical markers, electrophoretic loci, and RFLPs are compromised and not so useful for the assessment of population differences in diversity on a global scale. A landmark study of classical markers in humans revealed essentially no interesting patterns nor striking population differences (Cavalli-Sforza *et al*., 1994), while subsequent work on DNA sequences and on repeat polymorphisms invariably shows that diversity within populations is greater in African populations. The problem is ascertainment bias: the markers were discovered mostly in European populations, so the sample of marker loci available is biased toward loci that are

most variable in Europeans. This skews population diversity comparisons, and excess diversity in African populations is obscured. The human genome project has led to the discovery of a large number of single nucleotide polymorphisms (SNPs), millions of them, but the usefulness of these for population studies is again compromised by the ascertainment problem. The origins of the chromosomes used for discovery are not publicly known.

Some of this difficulty with ascertainment is overcome with the use of variable number of tandem repeat (VNTR) markers. VNTR loci are places on the chromosome where there are long stutters of a motif. For example, a locus where there are repeats of the nucleotide sequence ATAG would be a tetranucleotide polymorphism because the motif is four bases long. Short VNTRs, also called short tandem repeats (STRs) or microsatellites, with motifs of two to four repeats have been discovered and published in large numbers. Because of the high diversity of these markers, the ascertainment problem is not great, and they are useful for population comparisons (Rogers and Jorde, 1996).

In recent decades, technology has become available to make direct study of DNA sequences from populations possible. The first sequence collections published were from mitochondrial DNA because it is available at high concentrations in cells and is haploid (*see* Article 4, **Studies of human genetic history using the Y chromosome**, Volume 1 and Article 5, **Studies of human genetic history using mtDNA variation**, Volume 1). More recently, nuclear autosomal sequences have become widely available. In general, sequence data do not suffer from the ascertainment bias that interferes with interpretations of classical markers, RFLPs, and SNPs.

2. Measuring and describing variation

It is important to be aware of the distinction between purely descriptive statistics and interpretations of those statistics in terms of a model of evolution. Most of the statistics I discuss below can be justified in terms of an evolutionary model but they are perfectly useful and routinely used when the conditions of the model are violated. When they are model-bound, it is usually appropriate to make small corrections to account for estimation bias: these issues are treated well in Nei (1987).

Almost all descriptive statistics about variation measure average differences between entities, whether organisms or DNA sequences or repeat lengths. A common justification is that differences accumulate since the separation time of the entities and the statistics are estimates of that time. The time may be an average coalescence time between DNA sequences or, in the case of organisms, an average coalescence time over all the loci in those organisms that contribute to variation in the trait.

Much theory is based on the special case of neutral genes in a panmictic population that has been of constant size for a long time, 4 to 8 G generations where G is the number of genes transmitted in the population each generation. For quantitative traits of whole organisms, the assumption is that a large number of neutral mutations of small effect accumulate along the lines of descent of loci that affect the trait. For VNTRs, the assumption is that mutations cause alleles to change in length by single steps, that loss or gain of a motif are equally likely, and that allele

length is selectively neutral. For DNA sequences, the assumption is that mutations occur along the sequence according to a Poisson process, that the mutations are neutral, and that there is such a large number of nucleotide positions relative to the number of mutations that any single nucleotide position never experienced more than a single mutation event: this is the infinite sites assumption.

In the case of quantitative traits, the means, variances, and covariances among the traits, or, the logarithms of the traits, are the ordinary description of variation. If the heritabilities of the traits are known, then the covariance matrix among the traits can be transformed to be proportional to variation of genes underlying the traits. The heritability of a trait is the fraction of the variance that is due to variation in the additive effects of the underlying genes. When there are several traits, the heritability is a matrix, but in practice, detailed knowledge of heritabilities in natural populations is not available. Workers generally choose a plausible figure, perhaps 30 to 50%, and assume it applies to all the traits. An example of this approach is found in Relethford and Harpending (1994), who compared world human variation in craniometric traits with variation in classical markers and found the two data sets to agree closely.

Variation in a set of classical markers or RFLPs or SNPs is measured simply by averaging the expected heterozygosity over all the loci, where expected heterozygosity is computed by computing allele frequencies, then summing the product of each frequency and its complement over all the alleles. This sum has no theoretical interpretation because of ascertainment issues. It is possible to compare closely related populations but, as I mentioned above, global comparisons are apparently meaningless. As an example as part of a study of Ashkenazi Jewish genetics (Cochran and Harpending, 2004), we collected marker frequencies at 144 autosomal loci from several European populations from the excellent ALFRED website (ALFRED, 2004) maintained by Kenneth and Judy Kidd at Yale University. Relative to a baseline of 1.0 for mixed Europeans, the average heterozygosity of Ashkenazi was 0.988, of Russians 0.988, and of Samaritans 0.846. The reduced heterozygosity of Samaritans is a signature of the population bottleneck in their history, while the figure for Ashkenazi Jews, comparable to that of Russians, shows that there was no detectable bottleneck at all in Ashkenazi history. This is of interest because the high frequency of certain inherited disorders in Ashkenazi is often attributed to genetic drift during a bottleneck, but the data show no sign of a bottleneck.

Variation in a sample of STR data can be measured as heterozygosity, the probability that two alleles are not the same, but a better measure is allele size variance. The single-step mutation model of STRs leads to the expectation that the mean squared difference in size between two alleles is proportional to their coalescence time. The mean squared allele size difference is just twice the variance of allele size, so overall variation is computed as the average variance of all loci. Empirically this is not satisfactory because there are usually outlier loci with very large variances that dominate the results. In comparisons of variation between populations, it is better to work with rank-ordered differences in variance rather than with variances themselves. (Jorde *et al*., 1997).

There are two standard ways to measure variation in a collection of DNA sequences. One is the mean pairwise sequence difference (MPD), the average

number of nucleotide differences between all pairs of sequences. This is equivalent to heterozygosity computed at each nucleotide position and summed over all sites in the sequence. Since the number of mutations along a genealogy of a pair of sequences under a simple model is on average proportional to the length of the genealogy, MPD is another estimator of average separation time of a set of sequences. As an example, there is on the order of a single nucleotide difference between two human DNA sequences per 1000 nucleotide positions, so the MPD would be equal to 1 for kilobyte sequences, 5 for five kilobyte sequences, and so on.

Another statistic appropriate for sequences is the normalized number of segregating sites in the sample: under standard simplifying assumptions, the number of segregating sites divided by $\sum_{i=1}^{n-1} 1/i$, where n is the number of sequences, should be equal to the MPD. The difference between the two numbers is the basis of the Tajima statistic (Tajima, 1989) used to test for selection or demographic change in a population. This is the only statistic discussed in this article that is not a measure of the average separation time of chromosomes.

All the above statistics describe variation within a population. It is often of interest to describe how different populations are from each other, variation among populations. The simple way to do this is to use any of the above statistics to compute variation separately within each of the subpopulations, take the average, and call it V_s. Then pool the subpopulations as if they were all members of the same population, compute variation in this pooled sample, and call it V_t. From these, compute the fraction $F_{st} = (V_t - V_s)/V_t$ to describe the fraction of total variation that is between populations. This is invariably 10 to 15% among major human populations whether measured on metric traits, classical markers, VNTRs, or DNA sequences. Therefore, at neutral markers, the differences among major human populations correspond roughly to the differences among sets of half siblings from a random-mating population (12.5%) (*see* Article 2, **Modeling human genetic history**, Volume 1).

3. Interpreting pattern in diversity

So far I have discussed statistics that are single numbers that quantify the amount of diversity in a population. With many kinds of genetic data, there is more information to be gotten by looking at the patterning of diversity. With a collection of DNA sequences we can quantify diversity by the average pairwise sequence difference, but we can also look beyond the average at the distribution of all pairwise sequence differences. Similarly, the number of segregating sites is the basis of another number that quantifies diversity, as described above. Some segregating sites are present as singletons, sites where there is one nucleotide in a single sequence and another nucleotide in the $n - 1$ other n sequences, while other segregating sites may have each nucleotide present in several of the sequences. Sequences in a sample are tips of a tree of descent, and characteristics of the sample of sequences may allow us to infer characteristics of that tree and from there something about population history or natural selection at the locus.

Figure 1 shows the history of a sample of seven sequences from a population. As we go backward in time, the number of ancestors of the sample decreases as pairs

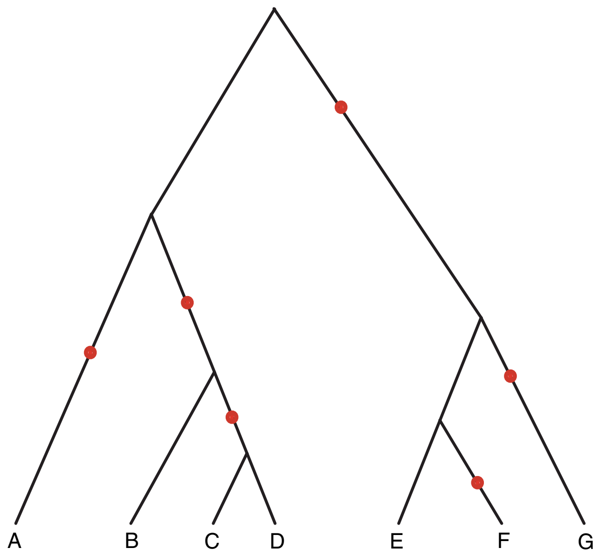

Figure 1 Gene tree showing the history of seven genes sampled from a population. The top of the tree, the coalescence of the sample, is usually 1 to 2 million years in the past for most human genes. Red circles show where mutations occurred

of sequences coalesce in common ancestors. For example, if there were two cousins in a sample of mtDNA sequences, daughters of sisters, then two generations ago their mtDNAs coalesced into the mtDNA carried by their maternal grandmother. We do not usually know what the tree that generated a set of data was like, but several simple statistics are useful to infer properties of the tree.

The tree in Figure 1 is typical of gene trees of neutral genes in populations that have not undergone drastic changes in size: the top of the tree for many human nuclear regions is on the order of 1.5 to 2 million years old. In the history of these sequences, six mutations occurred, indicated by circles on the tree. Mutations occur at random along the branches, and the probability of a mutation in any branch is proportional to the length of the branch. The oldest mutation in the tree is present in sequences E, F, and G, splitting the sample into 4 without and 3 with the mutation. Sequences B, C, and D share a mutation that also splits the sample into 3 with and 4 without. Sequences F, G, and A each carry a unique mutation, a singleton. Finally, sequences C and D share a mutation. If we tabulate segregating sites according to the number of copies of the mutation, we have 3 mutations that occur in 1 sequence, 1 that occurs in 2 sequences, and 2 that occur in 3 sequences. This tabulation is called a frequency spectrum, and we will see below that different demographic or selective histories can lead to different and distinctive frequency spectra.

Figure 2 shows a coalescence tree that looks very different from that in Figure 1: it is shaped more like a comb or a star. There are at first few coalescence events, going backward in time, but then coalescences occur rapidly. This tree might represent human mitochondrial DNA, with the top of the tree at about 200 000 years ago. Since the rate of coalescence at any time is proportional to the reciprocal of the population size, Figure 2 suggests that the population from

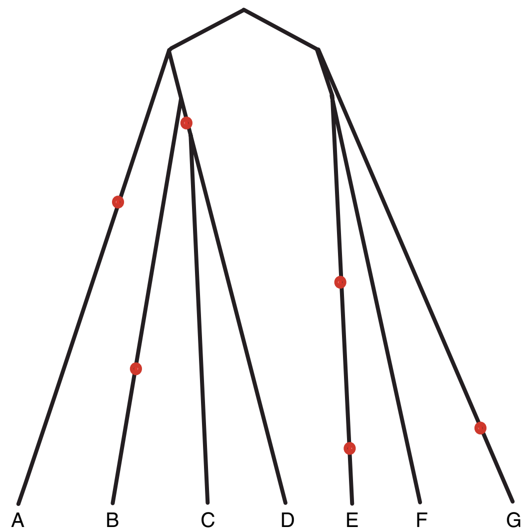

Figure 2 Gene tree showing the history of seven genes sampled from a population as in Figure 1. The population underwent population growth from a small number in the past, just after the coalescence. Human mitochondrial DNA has a history like this, with the top of the tree about 250 000 years ago

which we drew our samples was large until some time in the past, before which it was small so that coalescence events happened fast. In our sample of seven sequences from the tree in Figure 2, six are singletons while only one, that shared by sequences C and D, occurs in two of the seven sequences. This excess of singletons is a signature of a star-like gene genealogy, suggesting that an episode of rapid population growth generated the data. Another interpretation is that a new selectively advantageous variant occurred about 200 000 years ago and spread rapidly and that today's sequences are all derived from it. In general, we cannot distinguish between an episode of rapid population growth and a selective sweep of a new advantageous variant: both of these have been proposed to account for the clear star-like genealogical history of human mitochondrial DNA.

There is another property of the diversity portrayed in Figure 2 that is useful to compute. Imagine that there were many more mutations on the tree of Figure 2 that occurred at random along the branches. If we were to tabulate all possible pairwise sequence differences, they would all be similar because of the star-like structure of the tree. In Figure 1, sequences C and D are similar since not much time separates them, while in Figure 2 the difference between C and D is not very different from other pairwise differences. A histogram of pairwise differences is called a mismatch distribution, and a smooth unimodal mismatch distribution is a signature of a comb or star-like tree as in Figure 2.

Figure 3 shows a coalescence tree from a locus that has been under balancing selection. Selection that somehow favors a variant as it becomes less common can maintain separate gene lineages for much longer than they would persist if they were neutral. Figure 3 might represent, for example, the history of several human

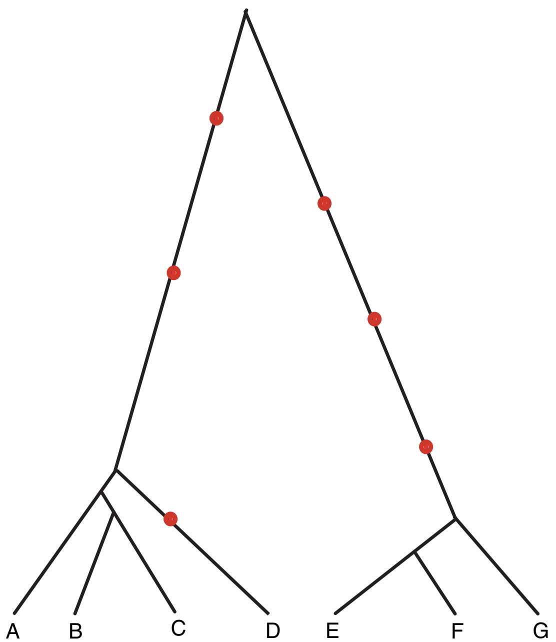

Figure 3 Gene tree showing the history of seven genes sampled from a population as in Figure 1. At this locus balancing, selection maintains both lineages in the population so the coalescence is very old. For human HLA system genes, for example, the top of the tree may be several tens of millions of years old

HLA alleles: in this system, uncommon variants are favored and alleles have deep gene trees, on the order of tens of millions of years.

Six random mutations are shown on this coalescence tree. Most of them are on the long deepest branches and divide the sample into 3 and 4: one mutation is present as a singleton, in chromosome D. The frequency spectrum has a "hump in the middle" in this case since there are more segregating sites with alleles of intermediate frequency than standard neutral theory predicts (*see* Article 7, **Genetic signatures of natural selection**, Volume 1).

There are standard statistics, provided by well-tested computer packages, that describe and quantify these insights, but their evaluation often involves complicated numerical calculations or even simulations. The simple graphical arguments given here are the bases for the more formal statistics.

Introductory Review

Human cytogenetics and human chromosome abnormalities

Terry Hassold
Washington State University, Pullman, WA, USA

1. Introduction

Modern human cytogenetics can be divided into three distinct eras, on the basis of the technologies that were available at the time. The first of these, the "golden era" extended from the late 1950s to about 1970. During this time, methodology was introduced, that made it possible to obtain karyotypes from a variety of tissues; most importantly, peripheral blood became amenable for study, making it possible to rapidly obtain cytogenetic information from virtually anyone. This quickly led to the identification of several common chromosomal syndromes, including Down syndrome, Klinefelter syndrome, and Turner syndrome.

These early studies were hindered by the inability to unequivocally identify each human chromosome, a limitation that was overcome by the introduction of chromosome banding techniques in the early 1970s. Thus, the second era of human cytogenetics, the "era of banding", began. Banding techniques made it possible to detect small structural chromosome rearrangements, such as deletions, duplications, or translocations that previously would have gone undetected. As a result, several new syndromes associated with deletions or partial trisomies were identified in the 1970s. Further, the ability to band chromosomes resulted in the emergence of important clinical applications of chromosome testing, for example, prenatal cytogenetic analysis and cancer cytogenetics. Initially restricted to laboratories in a few academic institutions, these fields quickly grew and are now common practice in clinical cytogenetic laboratories throughout the world.

The third era, "the era of molecular cytogenetics", began in the 1980s and continues today. It represents the fusion of conventional cytogenetic with molecular methodologies, and has led to the precise characterization of a number of new chromosomal disorders, including imprinting and other genomic disorders. The techniques that comprise molecular cytogenetics are discussed in detail in other chapters in this section (*see* Article 12, **The visualization of chromosomes**, Volume 1, Article 22, **FISH**, Volume 1, and Article 23, **Comparative genomic hybridization**, Volume 1). In the remainder of this chapter, we summarize the incidence and types of chromosome abnormalities that have been identified using these methodologies. We will focus on the first types of abnormalities

that were identified (i.e., conventional numerical and structural abnormalities), as several of the more recently identified types of abnormalities (microdeletion syndromes, imprinting disorders) are discussed in later chapters (*see* Article 17, **Microdeletions**, Volume 1 and Article 19, **Uniparental disomy**, Volume 1).

2. The incidence and types of human chromosome abnormalities

The normal diploid number of chromosomes in humans is 46, consisting of 22 pairs of autosomes and one pair of sex chromosomes (XX for females, XY for males). Because even the smallest autosome contains at least 200–300 genes, and imbalance of even a small number of genes is known to have profound effects on normal development, it might be expected that any kind of chromosome abnormality is problematic. Indeed, with rare exceptions this is the case and, considered as a class, chromosome abnormalities are the leading known cause of pregnancy loss and congenital birth defects in our species. In the following summary, we discuss the incidence and types of chromosome abnormalities, first focusing on abnormalities detectable on conventional cytogenetic analysis and subsequently briefly considering those detectable with specialized methodology.

2.1. "Old" chromosome abnormalities: numerical and "conventional" structural abnormalities

Early cytogenetic studies made it clear that a surprisingly high proportion of human conceptions are chromosomally abnormal. The vast majority of these are *numerical*, that is, involving too many or too few chromosomes, while a smaller proportion are *structural*, that is, resulting from breakage and reunion of chromosome segments.

There are four common types of numerical abnormalities in humans: trisomy, monosomy, triploidy, and tetraploidy, which cumulatively represent the leading genetic cause of mental retardation, congenital births defects, and pregnancy loss in our species.

Trisomy (the presence of an additional chromosome, leading to a diploid number of 47 rather than 46) is clinically the most important of these categories. Approximately, 0.3% of all liveborn infants are trisomic, with the most common single abnormality being trisomy 21, the chromosome complement responsible for most cases of Down syndrome. Occurring in approximately 1/600–1/800 liveborn infants, Down syndrome is associated with moderate to severe mental retardation and with a constellation of characteristic phenotypic features; by itself, it is the leading genetic cause of mental retardation in humans.

Sex chromosome trisomies are the next most common trisomies, resulting in individuals with 47,XXX, 47,XYY, or 47,XXY (Klinefelter syndrome) chromosome complements. Of these abnormalities, Klinefelter syndrome is the most serious clinically, as it is associated with infertility and frequently, mild cognitive or behavioral abnormalities.

Other trisomies are rare, owing to the fact that the phenotypic abnormalities prevent survival to term. However, they are extremely common among clinically recognized spontaneous abortions (miscarriages), accounting for at least 25% of all such conceptions. Trisomies for most chromosomes have been identified in spontaneous abortions, although there is enormous variation in the frequency of the different trisomies. For example, trisomy 16, the most commonly identified trisomy, accounts for approximately one-third of all trisomies identified in abortions and, together with trisomies 21 and 22, for one-half of all trisomies. Other commonly observed trisomies include trisomies 2, 13, 14, and 15. In contrast, certain trisomies (e.g., 1, 5, 11, and 19) are virtually nonexistent, presumably because they house genes that are vital for embryonic/fetal development.

Because of their clinical importance, a great deal of attention has been given to the genesis of human trisomies – how they originate and factors that may influence their likelihood of occurrence. Using DNA polymorphisms to trace the inheritance of the extra chromosome, studies of the last decade have made it clear that most trisomies originate from meiotic nondisjunction – that is, errors in cell division that lead to the presence of an extra (or missing) chromosome in the gametes (eggs or sperm). While errors in both oogenesis and spermatogenesis have been identified, meiotic divisions in the development of the egg appear to be the most susceptible to nondisjunction. Indeed, over 90% of all human trisomies appear to be attributable to maternal meiotic nondisjunction, with errors at the first meiotic division (MI) being the predominant source of trisomies. While the reason for this propensity to error remains unknown, it is likely due to the unusual biology of MI in the egg: the division is initiated before birth in the fetal female ovary, but arrests until the time of ovulation some 10–15 to 40–50 years later, at which time it is finally reinitiated and completed.

While a great deal is now known about the parent and meiotic origin of human trisomies, much less is known about factors that influence their frequency. One factor stands out: the association between increasing maternal age and trisomy, which is arguably the most important etiologic factor in human genetic disease. Among women under the age of 25, approximately 2% of all clinically recognized pregnancies are trisomic; by the age of 36, however, this figure increases to 10% and by the age of 42, to over 33%. This association between maternal age and trisomy is exerted without respect to race, geography, or socioeconomic factors. Thus it appears to be "hard-wired" into our species, although the evolutionary benefit that this provides, and its underlying molecular basis, remain obscure.

Until recently, increasing maternal age nondisjunction was the only factor known to influence the frequency of nondisjunction. However, studies of the past decade have finally detected a second contributing factor: abnormal meiotic recombination. Recombination is a process that occurs during the MI, involving pairing, synapsis, and exchange (crossing-over) between homologous pairs of chromosomes; it is discussed in more detail in another chapter (*see* Article 13, **Meiosis and meiotic errors**, Volume 1). Recombination results in the exchange of genetic material between homologs, thus acting to increase genetic diversity within a species. However, it has a second, sometimes overlooked, function. Specifically, the physical exchange of material serves to tether the homologs together during prophase of

meiosis I, thus facilitating their alignment on the metaphase I plate and increasing the chances of proper segregation at the first division.

From studies of model organisms, it had long been known that alterations in recombination increased the likelihood of nondisjunction. With the advent of DNA polymorphism analysis in the 1990s, it became possible to study the effects of recombination on human nondisjunction, and to ask whether, as in model organisms, human trisomies were associated with altered recombination. The results have been compelling. For all human trisomies yet studied, aberrant meiotic recombination is a major contributing factor. To date, three types of abnormal recombination patterns have been identified: (1) complete failure of recombination between homologs, leaving the homologs to wander at random at MI, (2) recombinational events in which the homologs are held together only at the tips of the chromosomes, presumably leading to "weak" connections that are unable to sufficiently bind the homologs together, and (3) recombinational events that occur close to the centromeres of the chromosomes, possibly leading to inter-homolog connections that are too "strong", preventing them from separating from one another at the first division.

The demonstration of a link between abnormal meiotic recombination and trisomies has provided the first molecular correlate for human nondisjunction. Intensive efforts are now underway to determine why such abnormal recombinational patterns occur in the first place, and whether these patterns may be responsible for some proportion of maternal age-dependent human trisomies.

Monosomy (the absence of a single chromosome, leading to a diploid number of 45 rather than the normal 46) is sometimes thought of as the "flip side" of trisomy. That is, a nondisjunctional event should lead to a gamete with a missing chromosome, as well as a gamete with an additional chromosome. Thus, it might be expected that monosomies and trisomies would occur in equal frequency. However, this turns out not to be the case, as monosomies are exceedingly rare. Indeed, only one monosomy, sex chromosome monosomy (45,X; the chromosome complement associated with Turner syndrome), is identified in any frequency. It is identified in approximately 1/20 000 newborns, who develop as phenotypic females, but with short stature, streak gonads, and infertility. For reasons that are not clear, the 45,X chromosome complement is much more frequent in miscarriages where it accounts for nearly 10% of all such conceptions.

Why are monosomies so rare? Likely, they occur at appreciable frequency but are eliminated very early in gestation because of the detrimental effects of haplosufficiency, that is, the presence of only one, rather than two, copies of a gene(s). Haploinsufficiency for a single gene is frequently associated with fetal demise or severe birth defects; therefore, it is not surprising that haploinsufficiency for an entire chromosome would be incompatible with embryonic development. Indeed, the fact that 45,X conceptions frequently survive long enough to be detected as clinically recognizable miscarriages or, much more rarely, as liveborn infants, is presumably attributable to X-chromosome inactivation (*see* Article 15, **Human X chromosome inactivation**, Volume 1). This is the process whereby one of the two X chromosomes in normal female cells is silenced, leaving only one functional, expressed copy for most X-linked genes. As no such process exists for autosomes, autosomal monosomies are much more lethal than is the 45,X condition.

Triploid conceptions have an additional whole haploid set of chromosomes, that is, 69 rather than 46 chromosomes. They are almost never identified in liveborn infants but are extremely common in miscarriages, accounting for nearly 10% of such conceptions. Triploidy can result from one of two processes: (1) failure of a meiotic division, resulting in a gamete with 46 chromosomes, for example, failure of MI in oogenesis, followed by fertilization by a normal sperm, leads to triploidy of maternal origin or (2) penetration of a normal egg by two sperm ("dispermy"), yielding triploidy of paternal origin.

Both types of triploidy have been identified but, intriguingly, the phenotypes are different: for example, paternal triploids are characterized by the overgrowth of the placenta, while maternal triploids are not. This "parent-of-origin" difference in phenotype is an example of an imprinting effect, which is discussed in more detail later (*see* Article 19, **Uniparental disomy**, Volume 1).

Tetraploid conceptions have two extra sets of chromosomes, that is, 92 rather than 46 chromosomes. These are identified only in miscarriage samples and apparently almost always result from failure of an early mitotic cleavage division.

2.1.1. Structural chromosome abnormalities

Structural rearrangements involve breakage and reunion of chromosomal material. Although much less common than numerical abnormalities, they have a special clinical significance since they can be inherited through generations. That is, for some types of structural rearrangements, clinically normal individuals may carry the rearrangement in "balanced" form but transmit an "unbalanced" form to their progeny, leading to phenotypic abnormalities. This is in contrast to numerical abnormalities, which arise de novo in meiosis or in an early mitotic division, and thus are not passed on from generation to generation.

Rearrangements may be interchromosomal (involving exchange of material between different chromosomes) or intrachromosomal (involving the reordering, loss or gain of genetic material on a single chromosome).

The most important classes of interchromosomal rearrangement are translocations, which are categorized as reciprocal or Robertsonian. Reciprocal translocations simply refer to situations in which material is exchanged between different chromosomes, resulting in "hybrid" chromosomes containing segments of each of the original nontranslocated chromosomes. By themselves, they do not cause problems, since the individual carrying them may have the same genetic material as a chromosomally normal individual. However, there are at least two ways in which translocations may result in phenotypic abnormalities: (1) the breaks that led to the translocation events may be complex, leading to loss of material surrounding the break points and consequently to genetic imbalance and (2) during meiosis in individuals heterozygous for translocations, complex structures link the translocated chromosomes with their structurally normal homologous partners, making it possible that the wrong combination of translocated and nontranslocated chromosomes will pass together into the gametes. This results in genetic imbalance for the translocated portions, which, depending on the length of the translocated segments, can have disastrous phenotypic consequences.

For the most part, reciprocal translocations occur randomly throughout the genome, that is, there are no “hot spots” for reciprocal exchanges. However, there is one notable exception to this rule: the 11;22 translocation. First described in 1980, the translocation involves the exchange of material between the long arm of chromosome 11 (at q23) and the long arm of chromosome 22 (at q11). Balanced carriers of the 11;22 translocation are themselves clinically normal, but if their progeny inherit the translocation chromosome 22 as an “extra” chromosome, they manifest the “der 22 syndrome”, with a distinctive set of abnormal phenotypic features (e.g., with abnormalities of the ear, heart defects, cleft palate, and mental retardation).

Unlike other reciprocal translocations, the points of exchange are identical among the several hundred different families in which the 11;22 translocation has been identified. Thus, the 11;22 translocation is a rare example of a recurrent reciprocal translocation, involving regions of chromosomes 11 and 22 that are susceptible to rearrange with one another. Recent molecular analyses of these regions has elucidated the reason for this: the breakpoints on each chromosome are located within similar AT-rich palindromic repeats, creating cruciform DNA structures that presumably facilitate the illegitimate transfer of material between the nonhomologous chromosomes during meiosis.

Robertsonian translocations are a special class of reciprocal translocation, in which the long arms of two acrocentric chromosomes (chromosomes 13, 14, 15, 21, and 22) are fused, creating a chromosome that contains virtually all of the genetic material of the original two chromosomes. If the Robertsonian translocation is present in unbalanced form, a monosomic or trisomic conception results. For example, approximately 3% of cases of Down syndrome are attributable to unbalanced Robertsonian translocations, most often involving chromosomes 14 and 21. In this instance, the affected individual has the normal number of chromosomes (46) but in addition to two structurally normal chromosomes 21, carries a translocation 14/21 chromosome. This results in triplication for genes on the long arm of chromosome 21, leading to phenotypic abnormalities identical to those associated with conventional trisomy 21. Similarly, unbalanced Robertsonian translocations involving chromosome 13 account for a small proportion of individuals with trisomy 13 syndrome.

In addition to interchromosomal rearrangements, there are several types of intrachromosome structural abnormalities, including inversions (in which a segment of the chromosome is “flipped”, so that the orientation of genes is in the opposite orientation from that on a structurally normal chromosome), isochromosomes (in which one part of the chromosome is a mirror image of another), rings (in which breaks at both ends of the chromosome are sealed together, forming a circular chromosome), duplications (in which a segment of the chromosome is present in two or more copies), and deletions (in which a segment is lost). Of these, deletions are clinically the most significant. Two of the best characterized deletions, involving loss of material on chromosome 4p and 5p, result in Wolf–Hirschhorn syndrome and cri-du-chat syndromes, respectively. In both instances, the deletion involves the loss of a relatively small chromosomal segment; nevertheless, both are associated with multiple congenital anomalies, profound mental retardation, and reduced life span.

2.2. *"New" chromosome abnormalities: microdeletion and imprinting syndromes*

In 1986, Roy Schmickel coined the term "contiguous gene syndromes" to describe genetic disorders that mimicked single-gene disorders but that resulted from the deletion of a small number of tightly clustered genes. It was proposed that many such deletions would be so small as to be undetectable cytogenetically, that is, they would be "microdeletions". Over the past two decades, the increasing application of molecular techniques has led to the identification of over 20 of these microdeletion syndromes; many of these have parent-of-origin effects ("imprinting disorders"). Several of these are discussed in later chapters (*see* Article 17, **Microdeletions**, Volume 1 and Article 19, **Uniparental disomy**, Volume 1), and will not be considered in detail here. However, in the following discussion, we focus on two types of these disorders, emphasizing some of the general principles that have emerged from their analysis: a microdeletion syndrome (velocardiofacial syndrome, VCF) and two complementary disorders exhibiting parent-of-origin effects (Angelman and Prader–Willi syndromes).

Deletions of chromosome 22 (at 22q11) are among the most common microdeletions yet studied, as they are detected in approximately 1/3000 newborns. The most common syndrome associated with these deletions, VCF syndrome, includes a number of phenotypic defects, for example, learning disabilities or mild mental retardation, palatal defects, and congenital heart defects. Occasionally, individuals with a microdeletion of 22q11 deletion are more severely affected and are diagnosed as having DiGeorge syndrome, which involves abnormalities in the development of the third and fourth branchial arches, leading to thymic hypoplasia, parathyroid hypoplasia, and conotruncal heart defects. In approximately 30% of these cases, a deletion at 22q11 can be detected with high-resolution banding; by combing conventional cytogenetics, fluorescence in situ hybridization (FISH) (*see* Article 12, **The visualization of chromosomes**, Volume 1 and Article 22, **FISH**, Volume 1) and molecular detection techniques (i.e., Southern blotting or polymerase chain reaction analyses), these rates improve to over 90%. Additional studies have demonstrated a surprisingly high frequency of 22q11 deletions in individuals with nonsyndromic conotruncal defects. Approximately 10% of individuals with a 22q11 deletion inherited it from a parent with a similar deletion.

Prader–Willi syndrome (PWS) and Angelman syndrome (AS) both involve abnormalities of chromosome 15. In 1981, David Ledbetter described a series of patients with PWS, a proportion of whom had a cytogenetically detectable deletion between 15q11 and 15q13. Subsequently, a number of AS patients were observed to have a deletion in the same region. This was curious, because the syndromes are very dissimilar – PWS is characterized by obesity, hypogonadism, and mild to moderate mental retardation, while AS is associated with microcephaly, ataxic gait, seizures, inappropriate laughter, and severe mental retardation. The resolution to this question came some years later, when it was recognized that the parental origin of the deletion determines which phenotype ensues, that is, if the deletion is paternal, the result is PWS and if the deletion is maternal, the result is AS. However, an additional complication to this story arose when it was recognized that not all individuals with PWS or AS carry the deletion; in fact, in both syndromes, many

of the patients have two normal chromosomes 15. For most such individuals, it turns out that the parental origin of the chromosomes 15 is again the important determinant. In PWS, nondeletion patients invariably have two maternal and no paternal chromosomes 15, while for most nondeletion AS patients the reverse is true. This indicates that at least some genes on chromosome 15 are differentially expressed, depending on which parent contributed the chromosome. Additionally, this means that normal fetal development requires the presence of one maternal and one paternal copy of chromosome 15. Errors resulting in a deviation from this situation (e.g., fertilization of an egg with a 24, X,+15 karyotype by a sperm with a 22, X,−15 karyotype) will result in an abnormal phenotype, either PWS or AS.

Chromosomes that behave in this manner are said to be imprinted, and it is likely that several – although certainly not all – human chromosomes are imprinted. Chromosome 11 must be one of these, since it is now known that a proportion of individuals with the overgrowth syndrome Beckwith–Wiedeman syndrome have two paternal, but no maternal, copies of this chromosome.

In addition to microdeletion and imprinting syndromes, there is now at least one well-described microduplication syndrome. This is Charcot-Marie-Tooth syndrome Type 1A (CMT1A), a nerve conduction disease previously thought to be inherited as a simple autosomal dominant disorder. Molecular studies conducted in the 1990s demonstrated that affected individuals are heterozygous for a duplication of a small region of chromosome 17 (17p11.2-12). This makes the reason for the inheritance pattern clear: one-half of the offspring of affected individuals would inherit the duplication-carrying chromosome.

3. Summary

Chromosome abnormalities occur with astonishing frequency in our species, with an estimated 20–30% of all fertilized eggs having too many or too few chromosomes, or carrying structurally abnormal chromosomes. In the following chapters, we discuss the techniques that have led to the identification of these disorders, and describe the phenotypic outcomes associated with different classes of chromosome abnormality. Additionally, for those abnormalities in which the information is available, the molecular basis for the abnormalities is described. However, it will quickly become apparent that for most abnormalities, this information is simply not there. One of the major challenges in human genetics is the identification of the molecular bases for these conditions, and the identification of etiological factors that influence their occurrence.

Introductory Review

The visualization of chromosomes

Stuart Schwartz
University of Chicago, Chicago, IL, USA

Chromosomes have been both understood and misunderstood for over the past century. As early as 1882, Walther Flemming was believed to have started the field of human cytogenetics by describing chromatin (chromosome) as the rod-shaped bodies that he microscopically saw in the nucleus of cells. He also coined the term mitosis as the division of cells. Both Theodor Boveri and Walter Sutton in 1903 independently hypothesized that units of heredity were carried on these (yet undefined) chromosomes. Knowing the importance of the human chromosome, the next logical step was to understand the true chromosome number in man. In 1912, Von Winiwater stated that he believed that women had 47 chromosomes and men had 48 chromosomes. And T. S. Painter, in 1923, showed that the "true chromosome" number was indeed 48. Given the crude equipment and methodologies that these investigators had at their disposal, it is laudatory that they were indeed so close.

The chromosome number in humans remained at 48 from 1923 to 1956; however, even during that time it became recognized that changes in chromosome number was probably responsible for phenotypic abnormalities. Several authors in the 1930s, including L. S. Penrose, believed that a change in chromosome number was the underlying cause of Down syndrome. In 1956, Tjio and Levan eloquently described the chromosome number in humans as 46 (Tjio and Levan, 1956). In their paper in *Hereditas*, they stated that "Before a renewed, careful control has been made of the chromosome number in spermatogonial mitoses of man we do not wish to generalize our present findings into a statement that the chromosome number of man is $2n = 46$, but it is hard to avoid the conclusion that this would be the most natural explanation of our observations." – a remarkable understatement for such a landmark finding. This finding did not occur in a vacuum as many advances in cytogenetics were used to make the chromosomes more readable. This included the use of colchicine as a mitotic inhibitor, the utilization of a fixative and, most notably, the development of a hypotonic solution, by T. C. Hsu in 1956, to help spread out chromosomes, making them more visible.

Up until this time, chromosome analysis was done using tissue preparations, such as testicular material from deceased prisoners that was used by Painter, or fetal lung fibroblasts as used by Tjio and Levan. Most of the work in 1956 consisted of cell culture establishment, colchicine pretreatment, hypotonic solution pretreatment, and

squashing. However, the cell culture technology was an impediment to the better visualization of chromosomes, and as pointed out in 1932 by J. B. S. Haldane, “A technique for the counting of human chromosomes without involving the death of the person concerned is greatly to be desired”. In 1960, Nowell and Hungerford published their work on short-term cultures using lymphocyte cultures, which were preferable to long-term cultures. These were effective due to the discovery of phytohemagglutinin, extracted from the common navy bean, which allowed for the stimulation and growth of lymphocytes in culture. This work allowed for a glorious period of human cytogenetics in which a number of syndromes were shown to be chromosomal in origin including the cause of Down syndrome by Lejeune, Trisomy 13 by Patau, Trisomy 18 by Edwards, as well as Turner syndrome (Ford), and Klinefelter syndrome (Jacobs and Strong) (Lejeune *et al*., 1959; *see also* Article 11, **Human cytogenetics and human chromosome abnormalities**, Volume 1). However, at this point, all of the analysis and visualization was done using solidly stained chromosomes and their limited differentiation through the differences and size and centromere placement.

The next major breakthrough in the visualization of chromosomes came from the differential staining of chromosomes. In 1970, Caspersson and his colleagues published a landmark paper describing the identification of human chromosomes by DNA-binding fluorescent agents. Caspersson was not a cytogeneticist, but used his knowledge of chemistry to ultimately develop the first method of identifying each individual chromosome (Caspersson *et al*., 1970; Caspersson, 1989). This work utilized a fluorescent microscope and was difficult for many labs to utilize. Therefore, when Seabright (1972) published her paper on the rapid use or trypsin for producing a banding pattern that could be visualized by light microscopy, this technology was readily used by most laboratories to both visualize and characterize chromosomes. Many other banding technologies were developed and utilized to better understand chromosome structure and to define chromosome abnormalities. These include, but are not limited to, C-banding, G11-banding, NOR staining, R-banding, T-banding, and Cd-banding. While these were highly useful when developed, most have been superceded by a variety of DNA probes used with fluorescence in situ hybridization (FISH), as will be described below. The development of banding techniques again revitalized the field of cytogenetics and allowed for the visualization and characterizations of syndromes involving deletions (Cri-du-Chat; Wolf–Hirschhorn), duplications, reciprocal translocations (9/22 translocations), Robertsonian translocations, and inversions (recombinant 8 syndrome).

Since all of the individual chromosomes could now be visualized, it became obvious that at times two pairs of chromosomes showed different numbers of bands, which could not be accounted for the differential condensation of the chromosomes. If chromosomes were visualized in prometaphase rather than metaphase, it produced a higher resolution and allowed for the detection of abnormalities not seen in routine chromosomal analysis. Yunis first described this methodology in 1976 and continued to illustrate its usefulness in clinical cytogenetics (Yunis, 1976; Yunis *et al*., 1978; Yunis and Chandler, 1978). While the initial methodology focused on synchronizing the cell cycle in cultures using methotrexate, many different methodologies were used to either synchronize cultures (e.g., use of

excess TdR) or to keep the chromosomes from condensing (e.g., the addition of ethidium bromide). Many submicroscopic deletions that are studied extensively today using FISH were initially described using high-resolution methodologies. These include the deletions seen in Prader–Willi and Angelman syndrome, the deletion in DiGeorge syndrome (*see* Article 17, **Microdeletions**, Volume 1), and the duplication in Beckwith–Wiedermann syndrome. This new methodology allowed for a higher resolution analysis of chromosomes, which most laboratories ultimately developed. New abnormalities and new syndromes were described, but cytogenetics mostly went into a period of senescence after the adaptation and utilization of this methodology.

Even after the introduction of high-resolution methodologies, it had become more apparent that there was a limitation to the resolution of chromosomes microscopically. In order to produce more resolution, many investigators tried to utilize a technique pioneered by Pardue and Gall in 1969, in which they utilized radioactive DNA for direct hybridization to chromosomes (Pardue and Gall, 1969). Their work was very successful as they utilized repetitive DNA for this hybridization. Other workers had varying success, and the technology was used in many instances for the chromosomal localization of known genes. However, this work was very time-consuming and tedious and was not ready to be used routinely by clinical laboratories. Simultaneously, both Pinkel and his colleagues and Ward and his coworkers were developing similar nonradioactive fluorescence technology. Pinkel *et al*.'s initial paper in 1986 opened the doors for the use of FISH for the study of chromosomes, although it took many years for laboratories to incorporate this technology into their routine work (Pinkel *et al*., 1986). Since its initial use, FISH has changed the face of cytogenetics, invigorated the field, and no laboratory can be considered complete without using the technology routinely (*see* Article 22, **FISH**, Volume 1).

Briefly speaking, FISH utilizes a DNA probe that has been labeled to hybridize to denature DNA on a slide. The initial probes were indirectly labeled with a hapten and then detected fluorescently. However, with advances in technology, almost all FISH is currently done using direct fluorescent labels. FISH can be utilized to study metaphase chromosomes or DNA in interphase cells whether from cultures or paraffin sections. As long as the DNA, that is to be studied, is not degraded, it can be analyzed using FISH. This technology has a phenomenal range in that not only can metaphase and interphase cells be studied but essentially any tissue with a nucleus can also be analyzed. Constitutionally, FISH is routinely used in interphase cells to rapidly detect aneuploidy and in metaphase cells to detect subtle deletions. The microdeletions (e.g., Prader–Willi syndrome), described above, that could previously only be detected with good high-resolution banding can now easily be detected with appropriate FISH probes. FISH has also been extremely useful in the delineation of structural abnormalities such as marker chromosomes, duplications, or derivative chromosomes by the simple use of or combination of alpha-satellite probes and/or chromosomes paints. More recently, a set of chromosome-specific subtelomere probes have been developed and used to detect cryptic rearrangements that have been missed with routine banding. Many of these rearrangements (either simple deletions or derivative chromosomes) have been too small to detect with routine banding, but contain enough loss or gain of genetic material to lead to

phenotypic anomalies. It is estimated that between 2 and 6% of individuals with mental retardation/dysmorphic features without a recognizable G-banded anomaly may have a cryptic rearrangement. Thus, it is apparent that our resolution (and visualization) of chromosomes have been increased 20-fold from about 3 Mb with the analysis of banded chromosomes to approximately 150 kb with directed FISH analysis looking for specific DNA alterations.

This increased resolution is also important and easily seen with somatic changes in chromosomes associated with cancer (*see* Article 14, **Acquired chromosome abnormalities: the cytogenetics of cancer**, Volume 1). For these specimens, the development of probes has mainly involved resources for the detection of specific rearrangements associated with a variety of leukemias and lymphomas (*see* Article 24, **Cytogenetic analysis of lymphomas**, Volume 1). Again, as for constitutional abnormalities, these probes can be utilized in both metaphase and interphase preparations. Thus, while a bcr-abl fusion in chronic myelogenous leukemia can easily be detected routinely in metaphase G-banded chromosomes, FISH can be utilized in interphase cells (when appropriate metaphase preparations are not available) to detect the fusion. Similarly, probes for the TEL-AML1 fusion are routinely used to detect this change as the underlying 12/21 translocation cannot usually be detected analyzing the banded chromosomes. These are just two examples showing how FISH has changed, how chromosomes are studied, and what can be detected. More specific examples of its use can be seen throughout this book.

Most of the FISH analysis described above and throughout the rest of the chapters in this book has been possible because of the advances in technologies and the development of a series of commercial probes for these FISH studies. Most work in clinical laboratories, whether doing subtelomeric analysis or studying specific translocations in cancer, is done with prepared commercial probes. However, the study of the Human Genome has been a veritable boom for cytogeneticists. The resources produced in the elucidation of the genome allows for the study of any region of chromosomes. As almost the entire genome has been sequenced, there are BAC probes readily available, for any location in the genome, to delineate any structural change or better describe a chromosome anomaly. These probes have now easily been used to show cryptic deletions and the complexity of changes in chromosomes and have immensely improved our detection of chromosome changes. Again, however, most of these analyses need to be used as a directed study of abnormalities in that specific areas can be studied as desired. However, it is the development of these resources that has led to the next milestone in cytogenetics, the utilization of comparative genomic hybridization with BAC arrays to detect and study chromosome anomalies. Comparative genomic hybridization has been utilized for many years (*see* Article 24, **Cytogenetic analysis of lymphomas**, Volume 1). In its inception, it is a technology where you take DNA from a specimen you are interested in studying, label that DNA, and then hybridize to normal metaphase chromosomes. Utilizing this technology, you could determine if there were any excess or deficiencies in the DNA sample studied. While this is a good technique in most hands, its resolution was limited to about 10 Mb, not necessarily adding any resolution to routine banding. However, with the delineation of the genome, the DNA of interest can be labeled and hybridized against a BAC array. This array can

contain BACs that are 1 MB apart, allowing for a resolution of this magnitude, not just for an area of interest but for the entire human karyotype (Fiegler *et al*., 2003; Greshock *et al*., 2004; Bignell *et al*., 2004; Ishkanian *et al*., 2004). While this work is still in the research stage, the potential it can provide is enormous and soon will allow visualization of the chromosomes past the bands and to the DNA backbone. These advances will not only allow us to have greater visualization of chromosomes but also allow for a better understanding of chromosome abnormalities over the next 100 years.

1. The general scheme of meiosis

The meiotic process involves two cell divisions, and is accordingly divided into two parts, meiosis I and meiosis II (Figure 1). As in mitosis, these divisions are subdivided into the stages Prophase, Metaphase, Anaphase, and Telophase, and thus a full meiotic process includes two of each of these stages. The meiotic process has been recently reviewed by Page and Hawley (2003) and Tease and Hultén (2003). The salient points of each stage are highlighted in Table 1.

Following DNA replication, cells enter meiosis, with each chromosome being composed of two chromatids held together at the centromere. Meiosis I includes a prolonged Prophase in preparation for the halving of chromosome number, this "reductional" division taking place at Anaphase I (AI). Prophase I (PI) is by tradition subdivided into Leptotene, Zygotene, Pachytene, and Diplotene, with an intermediate Diakinesis stage before Metaphase I (MI).

The preparation for the MI/AI spindle to carry its cargo of whole chromosomes (rather than chromatids as in mitosis) takes place at Prophase I and involves intimate pairing of all four chromatids of the maternal and paternal homologs. This intimate pairing (synapsis) is mediated by a proteinaceous structure, called the Synaptonemal Complex (SC). Breakage and reunion (crossing-over) between nonsister chromatids gives rise to configurations known as chiasmata. The chiasmata hold homologous chromosomes together locally during the next phase, when they separate at Diplotene. Following chromatin condensation during the intermediate Diakinesis stage, bivalents align on the MI plate.

It is generally accepted that at least one so-called obligate chiasma is necessary for a normal segregation to take place. The number of additional chiasmata required to be formed to ensure mechanical stability is associated with the length of the chromosomes (Hultén, 1974; Lynn *et al*., 2002; Tease *et al*., 2002; Tease and Hultén, 2004). Most importantly, mechanical stability in this context also involves appropriate orientation of maternal and paternal kinetochores (proteinaceous spindle

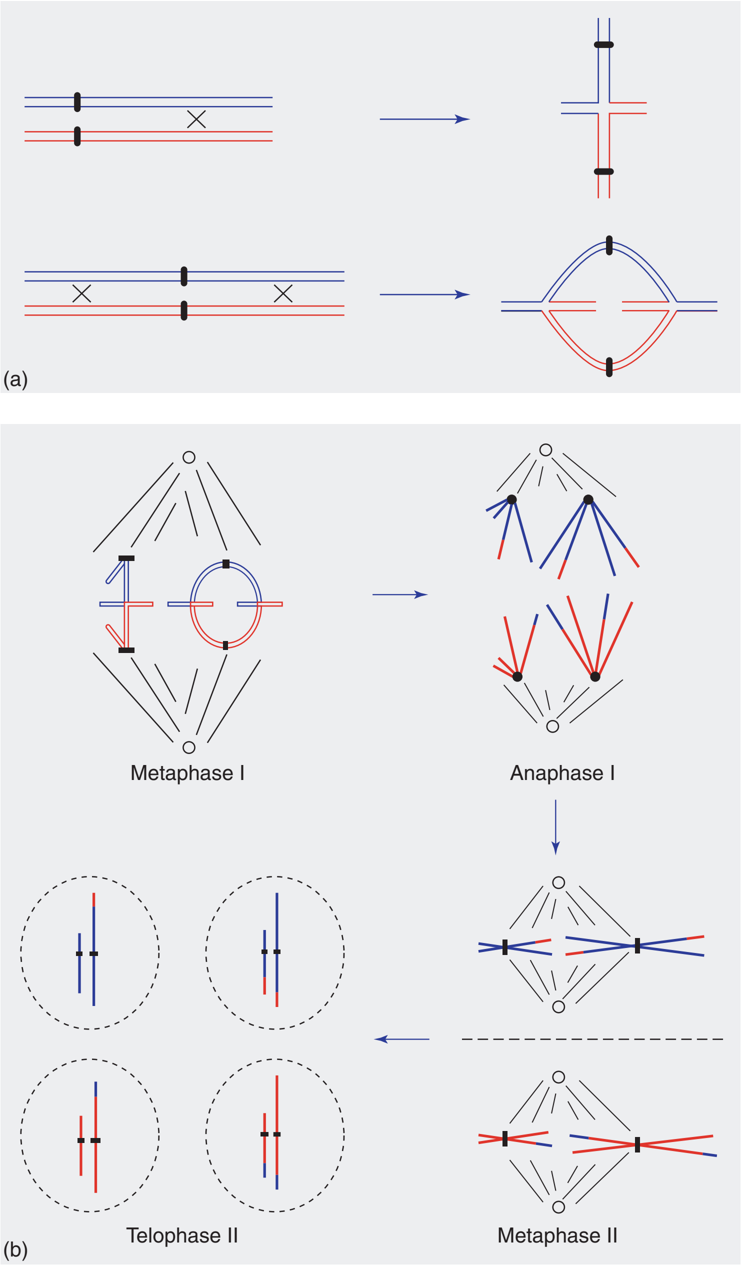

Figure 1 Schematic illustration of meiosis with (a) homologous chromosome synapsis, and crossing-over at the pachytene stage of prophase I and the derivative bivalents at MI, and (b) progression through metaphase I to anaphase I, metaphase II to anaphase II, and telophase II showing the four potential haploid gametes

Table 1 Salient points of meiotic stages

Stage	Subdivision	Features
Prophase 1		DNA replication of each chromosome to give sister chromatids held together at the centromere
	Leptotene	Start of chromosome condensation, formation of the lateral elements of the synaptonemal complex
	Zygotene	Chromosome pairing; completion of the formation of the synaptonemal complex
	Pachytene	Chromosomes fully paired, crossovers/chiasmata fully established
	Diplotene	Initiation of separation of the synapsed chromosomes
	Diakinesis	Chromosomes condense and become fully separated, except at points of crossing-over/chiasma formation.
Metaphase 1		Homologous chromosomes align on the equatorial plate with the kinetochores being the point of attachment to the spindles
Anaphase 1		Reductional division; homologous pairs separate, but sister chromatids remain together
Telophase 1		Formation of two daughter cells
Prophase 2		Nuclear envelope dissolves; creation of a new spindle
Metaphase 2		Chromosomes align on the spindle
Anaphase 2		Separation of centromeres; migration of sister chromatids to opposite poles
Telophase 2		Further cell division resulting in four potential haploid gametes from each parent cell

attachments at centromeres) normally facing opposite spindle poles at MI. This is facilitated by the topology of bivalents, where, for example, single-chiasma bivalents appear as cross configurations, doubles as rings, and triples as figures-of-eight. It is important to note that at AI (in contrast to the situation at mitosis) centromeres of homologs are kept together. The chance selection of the paternal and maternal kinetochores of any one bivalent to be presented to the opposite spindle poles leads to their random assortment in daughter cells. Each crossover event and chiasma formation give rise to a recombinant together with a nonrecombinant chromatid, which together are passed on to the daughter cells at AI, providing the basis for additional genetic variation in offspring.

After a brief PII without DNA replication, the two daughter cells complete meiosis II to produce four end products. This "equational" division is similar to mitosis. It should be recognized though that normally at least one of the sister chromatids (potential gametes) of each chromosome now is recombinant, containing a combination of variant genes (alleles) from the maternal and paternal homologs (Figure 2).

2. Variation between the two sexes

Interestingly, there are many differences in behavior between male and female germ cells during gametogenesis and meiosis. This includes the timing and continuity of events, the pairing and crossover processes, chromosome segregation, and the actual

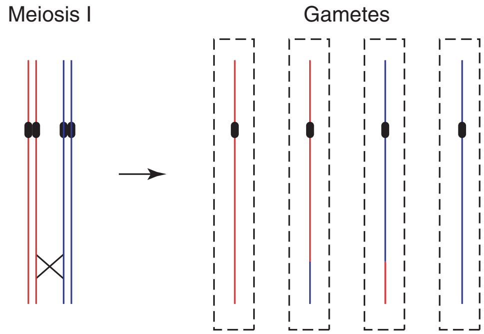

Figure 2 Schematic illustration of the relationship of a crossover, as viewed directly (as a chiasma or MLH1 focus) and the meiotic products (gametes). There are four chromatids, each a potential gamete, only two of which are recombinant

gamete produced – two cells as diverse as the oocyte and the sperm could hardly be imagined to derive from the same process! These differences are summarized in Table 2, and some of the more interesting aspects are discussed in more detail below.

2.1. *Timing of meiosis*

Meiosis in males starts after puberty and continues throughout life. On the other hand, meiosis in females begins around the 12th week of fetal life with homolog pairing, crossing-over, and chiasma formation up until around week 20. Oocytes arrest at the Diplotene stage, and are generally thought to undergo extensive cell death with numbers dropping from around 7 million to around 2 million at birth (Baker, 1963; Tilly, 2001). Meiosis resumes after puberty, when after the midcycle Luteinizing Hormone surge, chromosomes line up on the MI plate and undergo the reductional division at AI just before ovulation. This division is asymmetrical, where most of the cytoplasm is retained by one of the daughter cells, which will form the future mature oocyte. The other daughter cell forms a small polar body, which soon degenerates. Following progression through the second prophase, oocytes then arrest at MII until fertilization occurs. At fertilization, once the sperm has entered the oocyte and caused activation, oocyte meiosis continues through AII and TII, resulting in the ejection of the second polar body.

2.2. *The synaptonemal complex*

Meiotic chromosome pairing at PI involves three successive developmental stages, homolog recognition, presynaptic alignment, and intimate synapsis. This precisely timed process is mediated by the proteinaceous SC. The SC forms a protein scaffold for meiotic chromosome pairing taking place during PI, that is, during the substages Leptotene, Zygotene, and Pachytene. The SC then breaks down at Diplotene.

Table 2 Summary of the main differences between male and female meiosis

Male	Female
Meiosis is a continuous process from puberty throughout life, and can result in the production of around 200–300 million spermatozoa daily. A full cycle of spermatogensis takes approximately 120 days, of which 72–74 days are spent during meiosis.	Meiosis can take over 40 years from start to finish and only a few oocytes actually progress to the final stages, most being lost before birth.
Each parent cell produces 4 gametes (spermatozoa), all divisions being equal.	The two cell divisions are unequal with most cytoplasm retained in the oocyte and only a minor part forming the first and second polar bodies, thus only one actual gamete is produced from each parent cell.
The testis contains a population of stem cells that give rise to the continual supply of gametes.	Oocyte numbers appear to be limited to those present at birth with around 350 ovulating between puberty and the menopause. However in mice, recent experimentation has suggested the existence of stem cells that may constitute a reserve (Johnson *et al*., 2004).
Chromosome synapsis is initiated very near the ends of chromosomes in karyotypically normal, fertile men.	Interstitial initiation of synapsis is common in females.
Obligate chiasma formation is an efficient process.	Poor efficiency of obligate chiasma formation.
Lower overall chiasmata frequency.	Higher overall chiasma frequency.
Synaptonemal complexes are condensed.	Synaptonemal complexes are relatively decondensed, having almost twice the total length per cell compared to that in males.
Tendency of chiasmata to occupy preferential positions with hotspots near the ends of chromosomes.	Chiasmata occupy more interstitial positions.

The SC is a protein lattice that resembles railroad tracks and connects paired homologous chromosomes in most meiotic systems. The two side rails of the SC, known as lateral elements, are connected by proteins known as transverse filaments (reviews in Moens *et al*., 2002; Page and Hawley, 2004).

The SC was first discovered in mice and was later found to be evolutionarily conserved (albeit with species- and sex-specific modifications). Many antibodies against the proteins involved are available, providing tools for SC research using immunofluorescence techniques. Fluorescence in situ hybridization (FISH) methods have also been used sequentially to highlight the behavior of some of the SC proteins involved and their interaction with chromatin components during the meiotic chromosome pairing stages in human spermatocytes and oocytes (Barlow and Hultén, 1996; Barlow and Hultén, 1997; Barlow and Hultén, 1998a; Codina-Pascual *et al*., 2004; Hartshorne *et al*., 1999; Prieto *et al*., 2004; Sun *et al*., 2004; Lenzi *et al*., 2005).

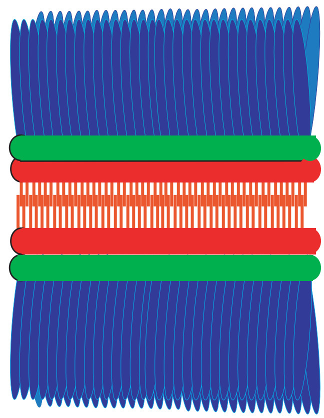

Figure 3 Schematic illustration of the SC

Even before meiosis is initiated, some "meiosis-specific" proteins, members of the cohesin complex (such as REC8 and STAG3) appear as diffuse aggregations within the cell nuclei. Subsequently, these cohesins function to stick chromatids together by interacting with the chromatin (DNA and proteins) of chromosomes to form initial cohesion axes.

During the initial development of the SC, most of the DNA form large loops emanating from the sides of the SC in a "chromatin cloud" (Figure 3). The chromatin is attached to the initially unpaired axial, and later, paired lateral elements of the SC by the cohesin proteins and the protein SYCP3 acting as "glue" between chromatids. These cohesion axes become "sandwiched" between chromatin and the SC axial elements marked by SYCP3. Pairing is subsequently stabilized at intimate synapsis, with transverse filaments developing between the lateral elements of the SC, forming a central element composed of proteins including SYCPI.

2.3. Chiasma formation

It is now generally accepted that initiation of crossing-over and chiasma formation in mammals takes place via double strand breaks (DSBs) induced by the protein SPO11 at Leptotene; and a range of proteins are involved in subsequent synapsis and recombination events (Bannister and Schimenti, 2004; Roig *et al*., 2004; Svetlanov and Cohen, 2004; Lenzi *et al*., 2005). Numerous DSBs (visualized by the γ-H2XA antibody) are initially created in DNA loops located outside the SC. Only a minority of this DNA subsequently becomes tethered to the core of the SC, exposing them to the recombinatorial machinery, associated with successive conversion and crossover events mediated by proteins such as RAD51 and MLH1 (Barlow *et al*., 1997).

The application of anti-MlH1 (MutL homolog1) to human SC preparations shows a labeling pattern consisting of distinct foci, always precisely associated with the SC and never in closely juxtaposed pairs (Figure 4). The frequency distribution of male MLH1 foci agrees with that of chiasmata at Diakinesis/MI (Figure 5); and

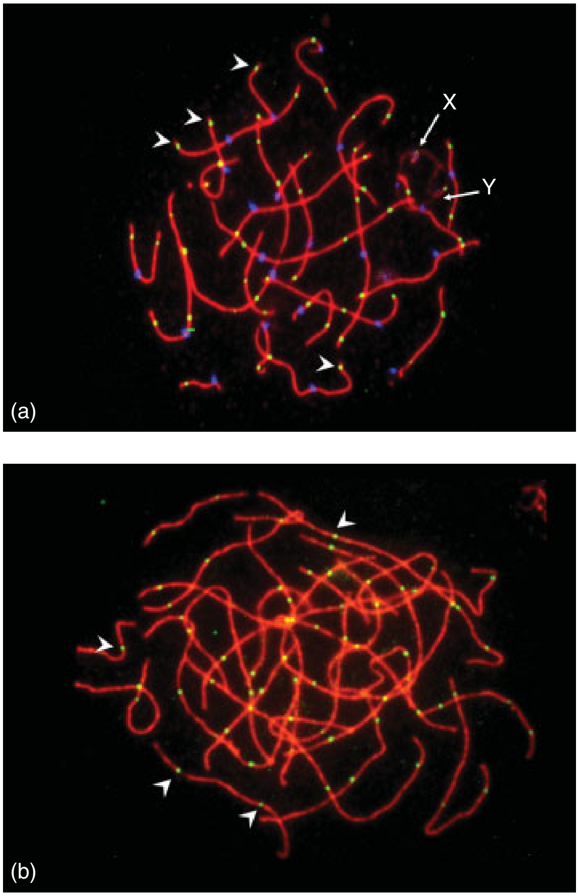

Figure 4 MLH1 foci on SCs of spermatocyte (left) and oocyte (right). Note the near-telomere preference in the spermatocyte and the higher number of foci in the oocyte

there is now no doubt that MLH1 is an appropriate marker for chiasma formation (Marcon and Moens, 2003).

The average crossover/recombination frequency estimated from MLH1 analysis in human males is around 50 with a range of 40–60 (Barlow and Hultén, 1998b; Lynn *et al*., 2002; Tease *et al*., 2002; Hultén and Tease, 2003a; Sun *et al*., 2004; Tease and Hultén, 2004), while that of females is around 70 but with a much larger variation between individuals than in males (Barlow and Hultén, 1998b; Tease *et al*., 2002; Roig *et al*., 2004; Tease and Hultén, 2004; Lenzi *et al*., 2005).

2.4. *Patterns of chiasma distribution*

A large database of patterns of chiasmata has accumulated over the last three decades by the study of Diakinesis/MI spermatocytes in preparations from testicular biopsy samples in human males, demonstrating that chiasma formation is a dynamic

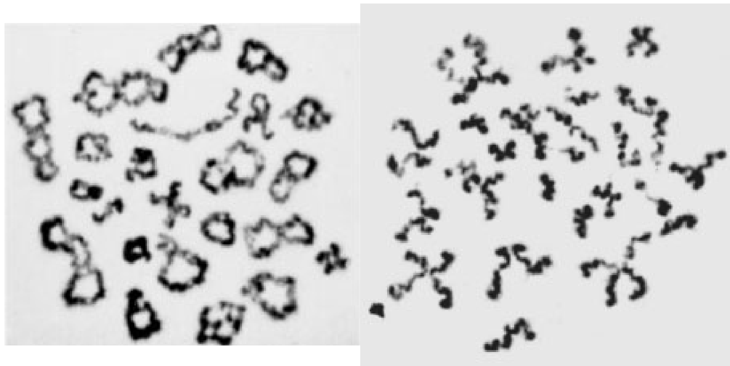

Figure 5 The morphology of MI and MII chromosomes is very different

process, varying between chromosomes, cells, and subjects (*see* Article 11, **Human cytogenetics and human chromosome abnormalities**, Volume 1 and Article 20, **Cytogenetics of infertility**, Volume 1). We have quite a good knowledge on the basic patterns and its variation between individual chromosomes, cells, and subjects in normal fertile men, as well as changes associated with infertility, and in carriers of structural chromosome rearrangements (review in Hultén and Tease, 2003a,b; Oliver-Bonet *et al*., 2004). On the other hand, our knowledge on the underlying mechanisms of regulation of this basic pattern and its variations is still very poor. For technical reasons, the same type of information on chiasmata at the Diakinesis/MI stage is not available in human females.

One important role of chiasma formation is to link chromosome pairs in such a way that whole chromosomes are conveniently transported to daughter cells at AI. Chiasma formation allows maternal and paternal homologs to be presented together to the MI-AI spindle so that daughter cells may receive a combination of these chromosomes rather than exclusively maternal or paternal homologs. Together with the random presentation of paternal and maternal kinetochores to opposite spindle poles, this provides the basis for the "infinite" genetic variability of offspring (*see* Article 16, **Nondisjunction**, Volume 1). The 3D topology of bivalents at this stage means that chiasmata are locked in their original positions owing to the behavior of bivalents during the transition from Pachytene through Diplotene and Diakinesis to MI (Hultén, 1990). This means that chiasmata do not need to "terminalize" in order to resolve. Thus, the long-held belief, originally proposed by Darlington, that chiasmata must terminalize in order to resolve is not a valid proposition.

3. Obligate chiasma formation and implications of chiasma failure

In the normally fertile human male, one chiasma is generally formed per bivalent, irrespective of its length; this chiasma is considered to be obligate to secure "regular" segregation of the chromosomes involved, by allowing the

maternal and paternal chromosomes of the bivalent to be properly orientated on the MI spindle. Failure of chiasma formation means that maternal and paternal homologs appear as disoriented univalents, leading to random rather than regular segregation. Daughter cells may thus receive a paternal, a maternal, both, or none of these (nonexchanged) chromosomes. One other complication of this situation is the potential for chromatids of univalent chromosomes to undergo precocious separation followed by disoriented segregation, leading to daughter cells receiving one, two, or no chromatids, instead of a whole (maternal, paternal, or recombinant maternal–paternal) chromosome. Univalent chromosomes are very rarely seen in male meiosis either during Pachytene (Barlow and Hultén, 1998b; Lynn *et al*., 2002) or at Diakinesis/MI (Hultén, 1974; Laurie and Hultén, 1985).

Efficient obligate chiasma formation in the human male stands in sharp contrast to the situation in females. Little information exists on patterns of chiasmata at the MI stage in human oocytes, however, recent SC and MLH1 observations on human fetal oocytes quite clearly demonstrate failure of synapsis and chiasma formation in a large proportion at the Pachytene stage (Tease *et al*., 2002).

4. Additional chiasmata, interference, and crossover hotspots

Numbers of additional chiasmata over and above the obligate are dependent on chromosome length (Hultén, 1974; Lynn *et al*., 2002; Tease *et al*., 2002; Tease and Hultén, 2004). Successive chiasmata are separated by large (many Mb) chromosome segments, a phenomenon termed chiasmata interference (Figure 6). Measurements of distances between MLH1 crossover foci on the SCs at Pachytene indicate interference distances in terms of physical SC length to be basically the same in human spermatocytes and oocytes (Tease and Hultén, 2004). This may "explain" the higher chiasma frequency in human females in comparison to males because the SCs in oocytes are relatively "decondensed" and much longer than in spermatocytes (Wallace and Hultén, 1985).

Chiasmata have a tendency for sex-specific preferential positioning (Figure 7) at crossover hotspots, occupying large (many Mb) stretches of chromosomes, which we may term megahotspots. A different type of preferential crossover positioning

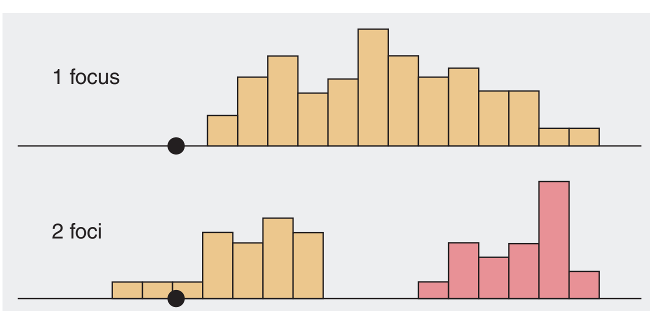

Figure 6 The distribution patterns of MLH1 foci on chromosome 21 SCs in oocytes illustrating the difference with one in comparison to two foci, which are widely spaced apart

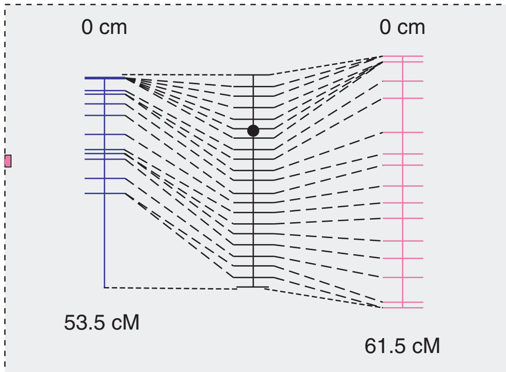

Figure 7 Genetic maps of chromosome 21 illustrating high amount of distal crossovers and the corresponding expansion of genetic length distally in the male (blue) in comparison to that in the female (red)

has more recently been revealed by DNA analysis of sperm. Comparison of certain DNA markers in somatic tissue (using e.g., blood samples) and sperm has demonstrated crossover hotspots stretching over a few kilobasepairs separated by longer noncrossover, so-called haploblock intervals, in the order of 50–100 kb. Such fine-scale hotspots were originally discovered because they may occur in the vicinity of hypervariable DNA sequences (minisatellites) that have been used extensively for "DNA fingerprinting" in forensics (Jeffreys *et al*., 1985). It has been suggested that these types of hotspots, which we may refer to as minihotspots, represent a general situation of "punctuate" preferential crossover positioning across the whole genome (review in Jeffreys *et al*., 2004). The relationship of these minihotspots to the megahotspots identified by MLH1 and chiasma analysis remains unknown, and requires further study.

5. Construction of genetic maps

Genetic maps illustrate the frequency of crossovers that on average take place along the length of each chromosome arm. The construction of genetic maps from crossover data obtained by cytogenetic analysis in individual cells has many advantages (review in Hultén and Tease, 2003b). First of all they allow sex-specific estimates of both intra- (intercellular) and interindividual variation in patterns of meiotic recombination with respect to the whole genome, individual chromosomes, and chromosome segments. They also distinguish between reciprocal recombination (crossing-over/chiasma formation) and other types of recombination events (such as sister chromatid exchange and conversion). In addition, the direct meiotic crossover analysis allows estimates of genetic map distances as well as recombination fractions from the same observed raw data.

Haldane (1919) originally defined the Morgan unit of genetic map distance as that length of a chromatid that has experienced on average one crossover per chromatid. Each chromatid in this situation corresponds to a potential gamete

(Figure 2). As each crossover event (MLH1 focus/chiasma) may give rise to two recombinant as well as two nonrecombinant gametes, the genetic map distance (Morgan, M) is calculated as half the average number of MLH1 foci or chiasmata in the interval concerned. In other words, the genetic map distance in centimorgans (cM) is obtained by multiplying the average number by 50, thus an average of 50 autosomal chiasmata in spermatocytes corresponds to a male genetic map length of 2500 cM, while 70 MLH1 foci in oocytes translate to a female genetic map length of 3500 cM. As already mentioned, these averages, however, hide a substantial interindividual variation in crossover frequency. Effectively, we all have our own average genetic maps with further individual specificity of the particular sperm and egg transmitted to offspring.

Assuming there is no chromatid interference but successive crossover chromatids are chosen by chance, then the corresponding recombination fraction is calculated as half the proportion of cells having one or more MLH1 focus/chiasma in the interval. Most human genetic maps have been constructed by tracing DNA markers through generations where the raw data are recombination fractions between markers (e.g., Kong *et al*., 2002; Cullen *et al*., 2002). This approach has the advantage that recombination data are linked to genes or DNA sequences. On the other hand, relatively large sample sizes of families/sibships are required, and importantly the analysis recovers only 50% of recombinants from each parental crossover event and only 25% of doubles. Assumptions are also required on the risk of double crossovers within the interval studied. Double crossovers involving the same DNA strand would cancel each other out, a phenomenon that is taken into account and compensated for by the use of the so-called mapping functions, estimating crossover/chiasma interference and thus the risk of double crossovers. Earlier linkage-based genetic maps showed large discrepancies in relation to those based on cytogenetic data with a general tendency for inflation of linkage-based genetic map lengths (likely due to overcompensation for presumed double recombinants) (*see* Article 54, **Sex-specific maps and consequences for linkage mapping**, Volume 1, Article 9, **Genome mapping overview**, Volume 3, Article 15, **Linkage mapping**, Volume 3 and Article 67, **History of genetic mapping**, Volume 4). The most recent ones, however, are very similar, at least as regards total genetic map length for each individual chromosome (Kong *et al*., 2002; Cullen *et al*., 2002; review in Hultén and Tease, 2003b). The high density of DNA markers now available should in our view make traditional mapping processes redundant. Previous complications in estimating genetic map distance by family studies due to misinformation as regards order of loci, should also now be much less of a problem, due to the detailed information on DNA marker order available from the Human Genome Project (Collins *et al*., 2004; *see also* Article 24, **The Human Genome Project**, Volume 3).

6. The transition from metaphase I to anaphase I

From Pachytene until MI, all four chromatids are “glued” together along their entire length (Figure 1). At MI, each pair of sister chromatids presents as a unit with both sister kinetochores facing in the same direction. This means that both sister

chromatids of a homolog are pulled to the same pole, once AI is initiated (review in Hauf and Watanabe, 2004). It appears from animal experimentation that AI chromosome segregation cannot start until all bivalents have orientated themselves on the MI plate with kinetochores of homologs facing opposite spindle poles, thus there may be a long delay before the onset of AI takes place. Once initiated however, this is seemingly a very rapid process, as indicated by, for example, the absence of any AI spermatocytes in preparations from human testicular biopsy samples.

A wealth of information about the complex interaction of proteins between kinetochores and spindle microtubules at the MI to AI transition has recently accumulated (reviewed in Nasmyth, 2002; Maiato *et al*., 2004; Hauf and Watanabe, 2004; Firooznia *et al*., 2005). A range of chromosome-associated proteins (either meiosis-specific or showing meiosis-specific behavior) have been identified including meiosis-specific cohesins, and centromere/kinetochore-associated proteins. The exactly timed behavior of these proteins ensures that normally all four chromatids are "glued together" until the onset of Anaphase I and retained within the centromere/kinetochore region until Anaphase II. It is also known that unattached kinetochores cause the delay of AI initiation through the action of several "wait" signals including Mad1/Mad2, Cdc20 and Bub1, localized to kinetochores (Howell *et al*., 2004; Vigneron *et al*., 2004; Shah *et al*., 2004; Taylor *et al*., 2004); subsequent attachment of these kinetochores then involves the activation of proteins forming the Anaphase Promoting Complex (APC). On the other hand, lapse of cohesion between chromatids, located peripheral to the chiasma, is obligatory to allow regular segregation of homologs at Anaphase I; and lapse of centromere/kinetochore-specific proteins is essential for regular Anaphase II segregation.

Activation of the APC in turn leads to Separase activation (Terret *et al*., 2003). Once activated, Separase is able to cleave cohesin complexes, allowing chromatids to separate along chromosome arms, initiating the MI-to-AI transition. It is important to note that only chromatid arm cohesion, necessary for separation of homologs is lost at AI. Sister chromatids remain connected via the action of amongst others, the cohesin REC8, STAG3, and Shugoshin at the centromere up until MII (Lee *et al*., 2003; Watanabe, 2004). It is not yet clear how the absolutely crucial protection of these cohesins from cleavage at centromeres during Meiosis I is regulated. Neither is it known why Meiosis I chromosome segregation is so error-prone in human females (see further below) in relation to males (and in relation to other mammalian species such as mice).

7. MII analysis for evaluation of AI segregation

Evaluation of the efficacy of AI segregation can be made by chromosome analysis of cells at the MII stage. Information in the male may be obtained by investigation of spermatocytes at MII, prepared from testicular biopsies in a way very similar to that used for making preparations from blood lymphocytes for somatic chromosome analysis. Cells are initially exposed to a hypotonic solution and then fixed in a (3:1) mixture of acetic acid and alcohol (Hultén *et al*., 2001). One particular problem here is that chromatids of individual MII chromosomes in spermatocytes prepared

this way often splay to the extreme and chromatids are often precociously separated. In addition they are loosely coiled and have a tendency to hook into each other (Figure 5). This makes even the counting of chromosomes problematic. Laurie *et al*. (1985) using stringent criteria to avoid artifacts did not detect any numerical abnormalities in 200 MII spermatocytes from six normal men with apparently normal mitotic karyotypes. Thus, there was no indication of either extra or missing chromosomes or indeed any extra or missing chromatids. To our knowledge no other studies have to date been presented on this issue. We may tentatively conclude that AI malsegregation in the human male is rare, and occurs with an incidence of less than 0.5–1% of cells.

This situation stands in sharp contrast to that in the human female. Chromosome analysis of a large population of oocytes at the MII stage has been performed. These studies demonstrate quite clearly that segregation errors involving both whole chromosomes and chromatids are common (review in Pellestor *et al*., 2003). It should be noted, however, that the material investigated so far consists almost exclusively of MII oocytes obtained at infertility (IVF) treatment, where spare oocytes, spontaneously arrested at MII, have been donated for research and used for karyotyping.

The morphology of oocyte MII chromosomes makes them much more amenable to karyotyping than is the case for spermatocytes; chromatids do not normally splay to the extent that they do in spermatocytes (Figure 5). Oocyte MII chromosomes are also more condensed and therefore more easily spread and separated from each other. A total of nearly 5000 human oocytes at the MII stage have been investigated with a view to obtain information on the efficacy of AI segregation as well as the occurrence of structural chromosome aberrations. Two types of methods have been used for making preparations including that of Kamiguchi *et al*. (1993), involving a gentle gradual fixation. Chromosome analysis has been performed by conventional (block staining as well as R-banding) methods, FISH for selected chromosomes and spectral karyotyping.

The largest study so far is that of Pellestor *et al*. (2002) involving 1397 MII oocytes, fixed by the Kamiguchi *et al*. (1993) technique and analyzed by R-banding. Numerical abnormalities were detected in around one-fifth (20.1%), mainly composed of extra or missing whole chromosomes or chromatids, while structural abnormalities (breaks, deletions and, acentric fragments) were much more rare, seen in 2.1% of cells. Numerical abnormalities caused by extra or missing chromatids were more common than aneuploidy of whole chromosomes, confirming the proposal by Angell that AI segregation errors of chromatids are common in human oocytes obtained through IVF studies (Angell, 1997). One very interesting observation in the Pellestor series is the strong positive correlation between maternal age and rate of aneuploidy, most pronounced as regards single-chromatids. The same has been seen in a small sample of fresh oocytes (not stimulated by hormone injections as part of IVF treatment) by spectral analysis (Sandalinas *et al*., 2002).

Another way of assessing AI segregation errors is by FISH analysis of the first polar body (review in Kuliev and Verlinsky, 2004). This has been achieved by micromanipulation of the polar bodies with subsequent FISH with 3–5 chromosome-specific probes as part and parcel of preimplantation genetic diagnosis (PGD) (*see* Article 21, **Preimplantation genetic diagnosis for chromosome**

abnormalities, Volume 1 and Article 22, **FISH**, Volume 1). Only the "aneuploidy-free" embryos have been transferred (following FISH analysis of the second polar body as well, as described further below). The largest study here is that summarized by Kuliev *et al*. (2003) involving 6733 oocytes from women above the age of 35 (average 38.5 years). In this series, a large proportion of oocytes were found to be aneuploid with respect to the chromosomes tested (chromosomes 21, 22, 13, 15, and 18). Thus, 41.7% of oocytes were considered to be aneuploid because of AI malsegregation, the majority again involving chromatids rather than whole chromosomes.

8. Gametic output

Investigations of chromosomes in mature gametes allow information to be obtained on the sum total of segregation errors including both AI and AII, as well as any structural chromosome aberrations that have occurred.

Chromosome analysis of mature gametes has primarily involved sperm (*see* Article 25, **Human sperm–FISH for identifying potential paternal risk factors for chromosomally abnormal reproductive outcomes**, Volume 1). Earlier studies were performed by the so-called humster technology (human sperm and hamster ovum pseudofertilization). This type of investigation is laborious and expensive, and has been restricted to a relatively few research groups. Guttenbach *et al*. (1997) reviewed observations by eight groups, involving over 20 000 sperm karyotypes from healthy donor men. Aneuploidy was detected in 1–3% of sperm. Another 5–10% showed structural chromosome abnormalities, many of which are presumed to have arisen postmeiotically, during differentiation of spermatids to mature sperm.

More recently FISH has been applied for analysis of selected chromosomes on very large populations of sperm from both chromosomally normal men and carriers of structural chromosome rearrangements. Shi and Martin (2000) have reviewed the experience gained on an impressive sample of more than 5 million sperm from around 500 normal fertile men, using one-, two-, or three-probe FISH. By and large, these studies have confirmed the findings using the humster technique that around 2–3% of mature spermatozoa are aneuploid.

Investigations of individual chromosomes indicate that their average numerical abnormality rate is around 0.1–0.2%. Only chromosomes 21 and 22 and the XY pair show slightly increased rates of sperm aneuploidy. The question whether some men may be predisposed to aneuploid offspring has not yet been answered with any certainty (Martinez-Pasarell *et al*., 1999; Soares *et al*., 2001a,b; Shi *et al*., 2001). On the other hand, tracing of DNA markers between fathers and XXY Klinefelter sons has demonstrated a reduced XY recombination, where the implication is that this has led to XY disomy in sperm (Thomas and Hassold, 2003; *see also* Article 19, **Uniparental disomy**, Volume 1).

FISH analysis of sperm from carriers of structural chromosome rearrangements, such as translocations, has shown a high rate of imbalance for the chromosomes involved (review in Shi and Martin, 2001; Oliver-Bonet *et al*., 2004).

As might be expected, there is much less direct cytogenetic information on gametic output including AII segregation errors in females. One intriguing way

of approaching this question is FISH analysis of not only the first polar body (as described above) but also the second polar body, obtained for analysis by micromanipulation at PGD treatment in pregnancies (review in Kuliev and Verlinsky, 2004). One example of this approach concerns the FISH study, summarized by Kuliev *et al*. (2003) on 6733 oocytes/fertilized eggs, where the conclusion was that AII segregation errors, as regards the chromosomes tested (chromosomes 21, 22, 13, 15, 16, and 18) had occurred in a slightly lower proportion of cases than AI errors, that is, in 30.7%. Remarkably, however, more than one-quarter were found to have both AI and AII segregation errors (27.6%).

9. Mechanisms of meiotic errors

Hardly anything is so far known from direct meiotic studies on the mechanisms of origin of structural chromosome rearrangements, including, for example, extra marker chromosomes, Robertsonian and reciprocal translocations, inversion, insertions, deletions, and duplications. Some of these may arise from breakage and repair processes taking place either pre- or postmeiosis. Special attention has been paid to the origin of de novo deletions and duplications, comprising the so-called genomic disease (Shaw and Lupski, 2004). The suggestion from somatic DNA marker investigations of children and their parents is that these chromosome disorders originate by misalignment of homologs at Meiosis I Prophase, followed by "ectopic" crossing-over/chiasma formation/recombination between similar (paralogous) DNA sequences, located at a distance from each other, either within the same homolog or indeed on different homologs. To our knowledge, no investigation has yet been performed to identify such ectopic crossovers directly by investigation of SCs. However, misalignment has been clearly documented in human oocytes, in which centromere signals (by the CREST antibody) are often staggered (Hartshorne *et al*., 1999).

Attention has focused on aneuploidy, which is a major cause of reproductive failure and congenital disease with special reference to common chromosome disorders such as Trisomy 21 Down, Trisomy 13 Patau and Trisomy 18 Edward Syndromes as well as the sex chromosome aneuploidies XXY Klinefelter, XYY, XXX, and X Turner syndromes. Much effort has been devoted to explaining in particular the maternal age effect especially noticeable as regards Trisomy 21 Down syndrome, this being the most common genetic disorder in humans.

It is known from previous indirect studies, tracking DNA polymorphisms between parents and children, that patterns of meiotic recombination (deciding the formation of bivalents and their shape) play an important role (Hassold and Hunt, 2001). However, it is not yet clear how this may work in detail. Most segregational errors underlying these aneuploidies have been found to take place at maternal AI; and it has, for example, been suggested that certain chiasma positions, such as a single distal chiasma of bivalent 21 may constitute a specific risk factor. On the other hand, the very same position is one of the most common in spermatocytes (Hultén, 1974; Laurie *et al*., 1985; Hultén and Tease, 2003b), where AI segregation errors are uncommon, and there is no known paternal age effect in this respect. Clearly a so-called second hit must be of paramount importance in handling such

oocyte bivalents differently from spermatocytes at a later stage. What would this be is yet unclear.

More detailed information on the intricate interaction between chromosomal and spindle proteins in oocytes at MI and AI in particular may provide some answers including an explanation for the well-known maternal age effect. Recent work indicates that knowledge obtained from the mitotic cell cycle may to some extent be extrapolated to meiosis, which opens up new avenues here. It has been suggested that age-related reduction in some proteins (such as the kinetochore-bound spindle checkpoint proteins Mad1 and Bub2 and/or the meiosis-specific cohesins) in combination with the specific spindle morphology and large size of the oocyte nucleus may play specific roles (review in Eichenlaub-Ritter, 2004). Quantitative analysis of the mRNA of some of these proteins has recently revealed an age-related degradation in human oocytes (Steuerwald *et al*., 2000). There is also a possibility that the morphology of the centromeres may contribute, where those with small amounts of specific (alphoid) centromeric DNA may be disadvantaged (Maratou *et al*., 2000). Furthermore, oocyte Anaphase I spindles have been shown to be barrel shaped rather than triangular as in spermatocytes. This may make the task of chromosome segregation more difficult. Remarkably, there are clear indications that Meiosis I spindles in oocytes obtained from older women are much more irregular than those from younger women (Battaglia *et al*., 1996; Volarcik *et al*., 1998).

Many factors may contribute to the formation of spindles including a range of spindle proteins, mitochondrial and hormonal status, follicle maturation in relation to the oocyte pool and peri-follicular microcirculation, and age-related changes in any of these factors may play a role.

Specialist Review

Acquired chromosome abnormalities: the cytogenetics of cancer

Susanne M. Gollin
University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA, USA

1. Introduction

Normal cellular growth is a delicate balance between cellular proliferation and cell death. Cancer is a disruption in this homeostasis, resulting in an imbalance favoring cellular proliferation over cell death. In the last several years, it has become clear that this homeostasis is controlled by genes (*see* Article 65, **Complexity of cancer as a genetic disease**, Volume 2). Thus, although some cases of cancer result from genetic predisposition due to germ-line genetic alterations that increase an individual's risk of developing cancer, cancer is a genetic disease of somatic cells (*see* Article 88, **Cancer genetics**, Volume 2). Both activation of oncogenes and loss (deletion, mutation, or inactivation) of tumor suppressor genes appear to be common in solid tumors, and altered regulation of oncogenes is prevalent in hematologic malignancies (Cavenee and White, 1995; Weinberg, 1996). This dysregulation is frequently caused by chromosomal abnormalities.

To describe the dysregulation of cancer genes, an automobile analogy serves us well. Oncogenes are dominant-acting cellular genes normally involved in the processes of cellular growth and proliferation. When one copy of an oncogene is mutated or otherwise deregulated, it functions in a manner similar to a "stuck accelerator pedal", resulting in uncontrolled cellular proliferation. Examples of oncogenes that are dysregulated in cancer cells include *CCND1* and *MYC* (Schwab, 1999). Tumor suppressor genes are recessive-acting "gatekeepers" of cellular proliferation; they may inhibit cell growth or promote cell death (Kinzler and Vogelstein, 1997). When both parental alleles of a tumor suppressor gene are mutated, lost, or otherwise inactivated in a somatic cell, it is as if the cell has "lost its brakes". Examples of such tumor suppressor genes altered in cancer cells are *TP53*, *RB1*, and *CDKN2A* (Sidransky, 1995). An additional family of genes critical to carcinogenesis is the DNA repair genes or "caretakers" of the genome (Kinzler and Vogelstein, 1997). These genes, including *ATM*, *MSH2*, and *MLH1*, maintain the "integrity" of the genome, playing key roles in DNA repair processes. Their role in cancer is comparable to experiencing a car problem when your mechanic was unavailable to repair it, thus leading to additional engine (DNA) damage.

Tumors develop as a result of deregulation of not one but multiple cancer-related genes. Alteration of three to six genes is thought to be necessary for tumor development. Mutations in additional genes result in increased cellular proliferation, disorganization, tumor progression, invasion, and metastasis (Vogelstein and Kinzler, 1993). Fearon and Vogelstein (1990) first proposed a linear pathogenetic schema for colon cancer, based on the concept that tumors develop and progress as a result of a distinctly ordered accumulation of tumor suppressor gene losses and oncogene activations, which endow a clonal population of cells with a proliferative advantage. The genetic changes in tumors may be conceptualized as a series of evolutionary events, which may have neutral, deleterious, or advantageous effects on the proliferation of a clone of cells. Neutral or deleterious genetic changes may result in stagnation or cell death, whereas advantageous events may result in a proliferative advantage, an increase in recruitment of blood vessels to the developing tumor, and/or the ability to metastasize. The Darwinian concept of "survival of the fittest" (Darwin, 1860) may be modified to "survival of the baddest", that is, those cells that can proliferate the most efficiently, vascularize, and metastasize, but they eventually defeat themselves by killing the host.

Cancer is a disease in which genetic alterations, most frequently chromosomal rearrangements, are acquired in somatic cells, resulting in loss of critical cellular checks and balances, resulting in dysregulation, proliferation, and ultimately, malignant transformation. According to Hanahan and Weinberg (2000), the "hallmarks of cancer" are defects in cell growth and proliferation, evasion of apoptosis, genome instability, sustained angiogenesis, and invasion and metastasis. Human cancer cells are characterized by cytogenetic alterations: numerical chromosomal alterations (aneuploidy), structural chromosomal alterations, and more frequently in carcinomas than hematologic malignancies or sarcomas, chromosomal instability. Aneuploidy results from the numerical chromosomal alterations. Further segmental chromosomal gains and losses come from structural chromosomal alterations, including reciprocal and nonreciprocal translocations, homogeneously staining regions, amplifications, and deletions. The cytogenetic aberrations in hematologic malignancies and sarcomas are frequently clonal, that is, the same abnormalities are present in multiple cells, all the progeny of one cell with a primary genetic alteration. In carcinomas, it is not unusual to find that each cell within a tumor has a different karyotype owing to chromosomal instability, which can be defined simply as numerical and structural chromosomal alterations that vary from cell to cell. Chromosomal instability is thought to be the means by which cells develop the features that enable them to become cancer cells (Hanahan and Weinberg, 2000). In spite of chromosomal instability, cancer cell karyotypes remain stable over time, probably because their genotypes have been optimized over their evolution for growth, making it less likely that additional genetic alterations will confer an additional growth advantage (Albertson *et al*., 2003).

2. Historical perspective and technical background

Chromosomal alterations and karyotypic instability in human tumor cells have been investigated for more than a century. In 1890, David Hansemann reported

that tumor cells with an abnormal chromosome constitution (aneuploidy) had abnormal mitotic spindles with extra poles and other chromosome segregational abnormalities (Hansemann, 1890). This aneuploidy theory was formalized in the early 1900s when Theodor Boveri, while studying chromosomal segregation in *Ascaris* worms and *Paracentrotus* sea urchins, suggested that malignant tumors arise from a single cell that has acquired an abnormal chromosome constitution (Boveri, 1929). Chromosomal cytology was advanced in the 1920s and 1930s by two technical improvements by plant cytologists, the squash technique that eliminated the difficulty in reconstructing and analyzing chromosomes from serially sectioned preparations and the application of the mitotic inhibitor, colchicine, derived from the Mediterranean *Colchicum* plant, to disrupt the mitotic spindle and increase the yield of mitotic cells available for chromosome analysis. In spite of these improvements, mammalian cytogenetics did not blossom until the 1950s, when hypotonic treatment was found to facilitate chromosome spreading, enabling visualization, counting, and analysis of individual chromosomes. In 1955, Tjio and Levan applied these new advances in cytogenetics to their cultures of human fetal lung tissues and discovered that the human chromosome number is 46 (23 pairs of autosomes plus the two sex chromosomes, XX in females or XY in males), rather than the previously reported 48. During this time period, Theodore Hauschka, Sajiro Makino, and Albert Levan each observed that tumor cell lines expressed both numerical and structural chromosomal aberrations. Soon afterward, Jerome Lejeune founded the field of clinical cytogenetics, by reporting that children with Down syndrome (then called mongolism) had 47 chromosomes due to trisomy 21. Cancer cytogenetics advanced in 1960, when Nowell and Hungerford reported the first chromosome abnormality in malignant human cells, the Philadelphia (Ph) chromosome, in chronic myelogenous leukemia (CML). Their finding supported Boveri's theory that cancer cells express chromosomal alterations. Major breakthroughs in cytogenetics occurred in the 1970s as a result of the development of chromosomal banding methods that enabled the identification of individual chromosomes as unique entities, based on their staining patterns (*see* Article 11, **Human cytogenetics and human chromosome abnormalities**, Volume 1 and Article 71, **Advances in cytogenetic diagnosis**, Volume 2). Classical karyotyping was formalized at the Paris conference in 1971 (and a subsequent meeting in Edinburgh early in 1972), when a uniform system of human chromosome identification based on the new chromosome banding methods was established. Current karyotyping practice involves analysis of 20 trypsin-Giemsa banded metaphase cells and karyotyping of at least two per clone. Cytogenetic nomenclature divides chromosomes into arms (p for petit and q, the next letter in the alphabet after p), and arms into regions, and regions into bands and subbands (ISCN, 1995). Thus, chromosomal locations are pronounced by chromosome number, arm, region, and band. For example, chromosomal band 11q13 is pronounced, "eleven q one three" rather than "eleven q thirteen", since 13 refers to region one band three and there are not 13 bands on the long arm of chromosome 11. Numerous additional classical cytogenetic banding methods have been developed to define chromosome structure and specific chromosome abnormalities.

Cytogenetic techniques critical to our understanding of genetic alterations in cancer cells are listed in Table 1. Molecular cytogenetic analysis, which blossomed

Table 1 Techniques useful in cancer cytogenetics

Cytogenetic technique	Application	Tissue preparation
Trypsin-Giemsa banding (G-banding)	Classical karyotyping	Metaphase spreads from cultured cancer cells
Fluorescence in situ hybridization (FISH)	Molecular cytogenetic analysis of targets defined by the DNA probe utilized, e.g., centromeres by α-satellite DNA, cosmid or bacterial artificial chromosome (BAC) clones of genes, etc. for detection of chromosome or gene copy number or gene mapping	Metaphase spreads or interphase nuclei from cultured cells, paraffin or frozen sections, touch preparations, cytology brush preparations, or dissociated tissue biopsies
Chromosome painting	Molecular cytogenetic analysis of specific chromosomes or chromosome segments	Metaphase spreads from cultured cancer cells
Spectral karyotyping or multiplex FISH	Molecular karyotyping using a set of chromosome-specific DNA probes, each labeled with a different dye or dye combination, to distinguish each of the human (or mouse) chromosomes as unique	Metaphase spreads from cultured cancer cells
Comparative genomic hybridization (CGH)	Comprehensive screen of the genome for segmental gains and losses using DNA isolated from test tissue (e.g., tumor cells; labeled in green) and control DNA (labeled in red)	Normal control male metaphase chromosomes; high molecular weight DNA isolated from cancer cells

in the late 1980s and continues to advance, has revolutionized the field of cytogenetics, particularly, cancer cytogenetics. The primary technique used for molecular cytogenetic characterization of chromosomes is fluorescence in situ hybridization (FISH) (Landegent *et al*., 1987; Cremer *et al*., 1988; Trask, 1991; Lichter and Ried, 1994; *see also* Article 22, **FISH**, Volume 1). This method involves hybridization of one or more fluorescently labeled DNA probes to metaphase chromosomes and/or nuclei. The most common form of FISH involves hybridizing a fluorescently labeled DNA probe (or a hapten-labeled DNA probe that can later be detected by a fluorescent tag) to a gene or DNA segment of interest and a different colored fluorochrome-labeled control probe (that maps to the same or a different chromosome) to metaphase spreads from a tissue or cells of interest. Cancer-related applications include mapping tumor-related genes or enumeration of gene or chromosome copy number in the context of deletions, amplifications, or ploidy changes. FISH hybridization to interphase nuclei (in paraffin or frozen sections, touch preparations, cytology brush preparations, or from harvested, dissociated tissue) is quite useful in cancer cytogenetics. Optimally, 200 cells are examined for this type of analysis. The results might also provide an indication of ploidy.

Interphase FISH eliminates the necessity and time of cell culture and enables enumeration of gene copy number compared to a control probe on the same chromosome in large populations of cells by molecular karyotyping of interphase nuclei even in the absence of metaphase chromosomes. However, FISH analyses only identify alterations of the targeted DNA probe(s), and do not detect other alterations, such as chromosomal abnormalities that may be important for a particular diagnosis or prognosis in a cancer patient. Therefore, at the present time, it is critically important that FISH be used as an adjunct to classical cytogenetic analysis and not as a "stand-alone" test. Another FISH method, chromosome painting, utilizes a cocktail of fluorochrome-labeled DNA probes from a chromosome or selected chromosomal region to localize those sequences in metaphase spreads from a tissue of interest (Pinkel *et al*., 1988; Ried *et al*., 1998). Chromosome painting enables identification of the origin of chromosomal segments involved in translocations and characterization of marker chromosomes, the origin of which is refractory to definition by classical cytogenetic methods. When examined using standard fluorescence microscopy, painting of two or more differentially labeled chromosomes in interphase nuclei results in beautiful multicolored nuclei, but provides little specific structural information owing to overlap of the chromosomal domains, which can only be resolved by computerized optical sectioning using confocal or other sophisticated computer-controlled microscopy.

Two new variations of chromosome painting that are extremely useful in cancer cytogenetics are spectral karyotyping (SKY) and multiplex FISH (M-FISH) (LeBeau, 1996; Schröck *et al*., 1996; Speicher and Ward, 1996; Speicher *et al*., 1996). These methods distinguish the 24 different human chromosomes (22 autosomes and two sex chromosomes) using a set of chromosome-specific DNA probes, each labeled with a different array of one or more fluorescent dyes and FISH hybridization to metaphase chromosomes. The detection and classification of the rainbow of probes utilizes different strategies, both involving CCD cameras and computer algorithms, with SKY taking advantage of Fourier spectroscopy to resolve the multicolored probes and M-FISH using multiple optical filters and image superimposition. Combinations of these classical and cytogenetic methods are essential to fully characterize the karyotypic alterations in cancer cells.

A common problem in cancer cytogenetics is a low mitotic index and the consequent lack of metaphase chromosomes to analyze and karyotype. Comparative genomic hybridization (CGH) is a form of FISH that comprehensively screens the genome for gains and losses of DNA segments (Kallioniemi *et al*., 1992; Du Manoir *et al*., 1993). The advantages of CGH are that it provides an overall picture of genomic imbalances in a tumor, eliminates the need for cell culture, and thus overcomes the primary difficulty of karyotyping tumors. The disadvantages of CGH are that it cannot detect balanced chromosomal rearrangements, such as translocations or inversions, and it cannot suggest the manner of loss in terms of chromosome rearrangements (i.e., whether loss of a segment is due to a deletion or an unbalanced translocation). Further, CGH can only detect relatively large genetic aberrations (such as gains of at least 2 mB and losses on the order of 10 mB). Moreover, the smallest abnormalities are only detectable by CGH when present in the vast majority of the cells (∼85%) in the population(s) from which the DNA was isolated, and larger abnormalities must be present in the majority of cells

(∼70%). Like other molecular methods that average the results, CGH analysis of tumor specimens is hampered significantly by the genetic heterogeneity seen within tumors and the frequent admixture with normal cells. This procedure is facilitated by commercially available imaging instrument and computer systems combined with sophisticated proprietary software. Newer advances include array CGH, a method involving the use of DNA microarrays containing specifically spaced, mapped markers distributed throughout the genome that are then hybridized and the ratios are linked to segmental gains and losses (Pinkel *et al*., 1998). The advantage of array CGH over cytogenetic CGH is higher resolution. The significant disadvantage at present is that high-resolution arrays are not readily available to the scientific community.

Advances in cancer cytogenetics have led from the discovery of the Ph chromosome to the characterization by Janet Rowley of the Ph chromosome as a reciprocal translocation between chromosomes 9 and 22, t(9;22)(q34;q11.2) (Figure 2). Identification of the Ph translocation, whether by classical or molecular cytogenetic methods or molecular genetic techniques, is now essential for diagnosis of patients with CML, although the Ph chromosome may also be observed in some patients with acute lymphocytic leukemia (ALL) and less frequently, acute myeloid leukemia (AML). Characterization of the Ph chromosome in CML led to cloning of the Philadelphia translocation breakpoint and the discovery that the translocation creates a hybrid gene consisting of 5′ regulatory and coding sequences of the *BCR* gene on chromosome 22 joined with 3′ coding, polyadenylation, and termination sequences from the *ABL* proto-oncogene on chromosome 9. This BCR/ABL rearrangement may be identified by FISH, a molecular cytogenetic method described earlier (Figure 5). The new chimeric gene formed by the Philadelphia translocation codes for a protein with enhanced tyrosine kinase activity. Identification of this protein led to the development of an effective new drug, Gleevec®, which inhibits this tyrosine kinase, blocks cellular proliferation, and induces apoptosis in cells expressing the Ph chromosome. Thus, clarification of the cytogenetic aberrations in a cancer enables not only diagnosis, but molecular characterization of the breakpoints, identification of the genes involved, description of the molecular pathology of the malignancy, and development of targeted therapies. As noted recently by Rowley (2001), cytogenetic identification and subsequent molecular cloning of translocation breakpoints has become one of the most efficient tools for identifying genes involved in malignant transformation.

3. Clinical applications of cancer cytogenetics

Over the past four decades, it has become clear that acquired, nonrandom chromosome abnormalities are associated with specific malignancies, particularly hematologic malignancies and sarcomas, although other alterations are characteristic of carcinomas, either individually or as a group (Table 2; Figures 1–5). The diagnosis of hematopoietic and lymphoid malignancies has been codified recently by the World Health Organization (WHO) (Jaffe *et al*., 2001). Cytogenetic studies are valuable for determining the diagnosis and prognosis of specific cancers and serve as independent etiologic or prognostic risk factors even when age, white blood

Table 2 Most common clonal chromosomal abnormalities in malignancies[a,b]

Malignancy	Consistent chromosomal abnormalities	Specific genes involved
AML	t(8;21)(q22;q22)	*AML1/ETO*
Acute promyelocytic leukemia	t(15;17)(q22;q12)	*PML/RARα*
AML with abnormal bone marrow eosinophils	inv(16)(p13q22)[c] or t(16;16)(p13;q11)	*CBFB/MYH11X*
AML	11q23 rearrangements	*MLL*
Chronic myelogenous leukemia (CML)	t(9;22)(q34;q11.2)[d]	*BCR/ABL*[g]
Precursor B-cell acute lymphoblastic leukemia	t(9;22)(q34;q11.2)	*BCR/ABL*
	t(4;11)(q21;q23)[e]	*MLL2(AF4)/MLL*
	t(1;19)(q23;p13)	*PBX/E2A*
	t(12;21)(p12;q22)	*ETV/CBFA*
Burkitt lymphoma	t(8;14)(q24;q32)	*MYC/IGH@*
Follicular lymphoma	t(14;18)(q32;q21)	*IGH@/BCL2*
Mantle cell lymphoma	t(11;14)(q13;q32)	*CCND1/IGH@*
Anaplastic large cell lymphoma	t(2;5)(p23;q35)[f]	*NPM1/ALK*
Alveolar rhabdomyosarcoma	t(2;13)(q35;q14)	*PAX3/FOXO1A*
Ewing sarcoma	t(11;22)(q24;q12)	*EWSR1/FLI1*

cell count, classification, and cell surface markers are evaluated. The new WHO classification of hematopoietic malignancies is the first to formally recognize the importance of genetic alterations in the diagnosis of leukemias, especially with regard to AMLs. Several types of AML are classified specifically on the basis of the cytogenetic aberrations present in the cells (Table 2; Figure 1). A cytogenetic alteration may be used to diagnose a particular malignancy on the basis of the specific association of the aberration with the disorder even when other diagnostic criteria are equivocal. Moreover, specific chromosomal abnormalities in malignancies may be associated with specific etiologies, such as loss of one chromosome 5, one chromosome 7, or deletion of the long arm of one chromosome 5 or one chromosome 7 in patients with AML after exposure to organic chemicals (such as dry cleaning or furniture refinishing solvents) or mutagenic therapy. Specific chromosomal alterations are often associated with a good prognosis. In AML, the t(8;21), t(15;17), and inv(16) rearrangements (Table 2) are usually associated with a favorable response to therapy and long-term survival (Grimwade *et al*., 1998). A complex karyotype, loss of one chromosome 5 or one chromosome 7, deletion

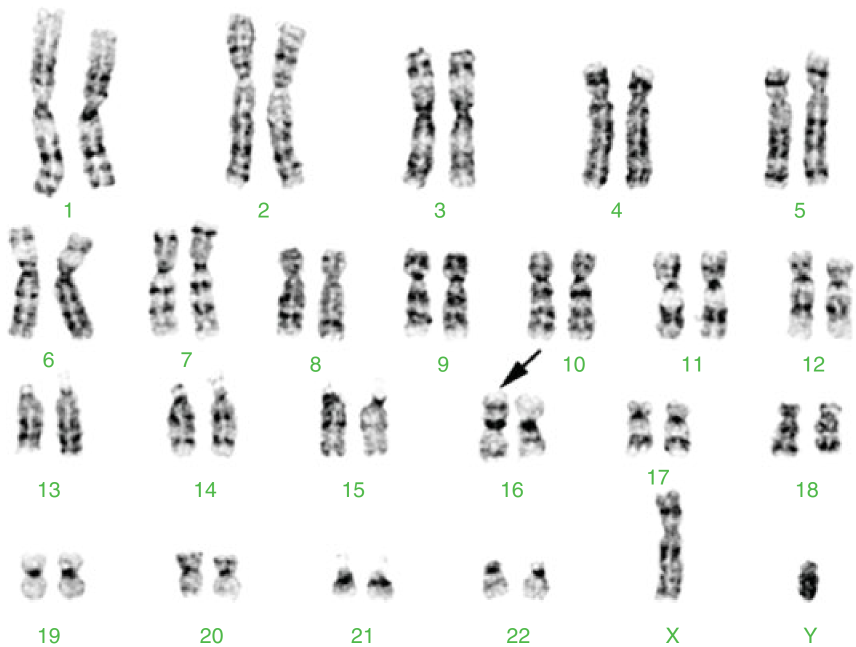

Figure 1 Karyotype from a 10-year-old female with acute myeloid leukemia (AML) with abnormal bone marrow eosinophils and the characteristic inverted chromosome 16 (arrow). This inversion results in a fusion between *CBFB* on the long arm that codes for a subunit of a DNA binding protein complex and the *MYH11* gene on the short arm that codes for the smooth muscle form of myosin heavy chain protein. The fusion protein is thought to interact with the AML1 transcription factor and increase its ability to bind to DNA and regulate transcription. 46,XX,inv(16)(p13q22)

of the long arm of one chromosome 5 or one chromosome 7, and/or abnormalities involving the long arm of chromosome 3 are associated with a relatively poor prognosis in AML. In addition to the diagnostic and prognostic usefulness of cytogenetics, a change in the karyotype of the abnormal cells from a patient often precedes progression of their malignancy. Disease relapse in a patient following bone marrow transplantation may also be heralded by the reappearance of host cells with acquired chromosomal abnormalities that may have been observed prior to transplantation. Thus, chromosomal abnormalities are common in human cancer cells and may provide useful diagnostic and prognostic information.

Cytogenetic alterations often point to the genes involved in the development and/or progression of malignancies. Numerous chromosomal translocation breakpoints have been cloned, and the genes, regulation of which has been altered by those translocations identified. These genes belong to specific functional families that are involved in the regulation of cellular growth (see Rowley, 2001, Table 1). Genes altered in cancer cells are important targets for the development of designer drugs to limit aberrant cellular proliferation. The example of the Ph chromosome was discussed earlier. Identification of the altered gene product in CML, a novel tyrosine kinase resulting from this translocation led to Gleevec®, a targeted

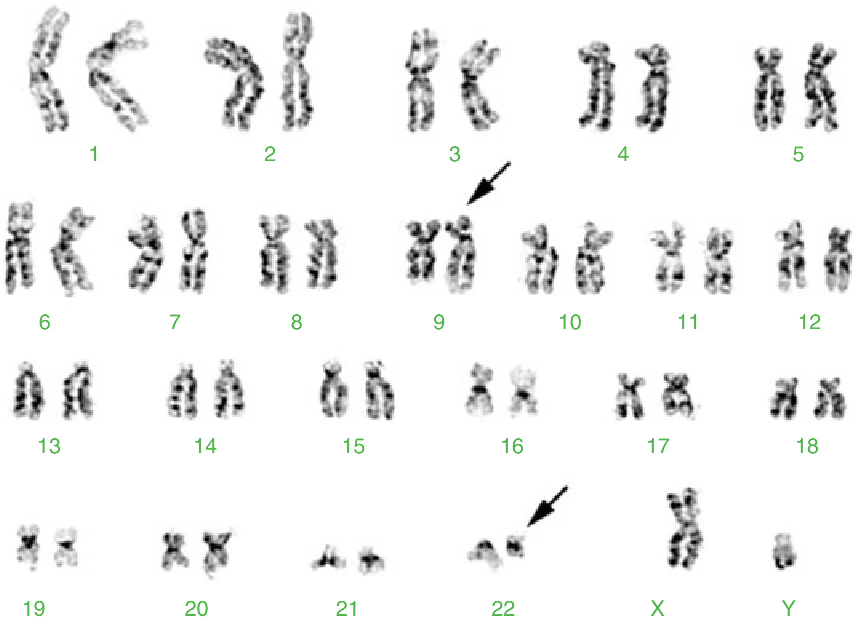

Figure 2 Karyotype from a 33-year-old male presenting with chronic myelogenous leukemia (CML). 46,XY,t(9;22)(q34;q11.2). See text for details about this translocation. The derivative chromosomes 9 and 22 are marked by arrows

(designer) therapy, with significant efficacy in CML and several solid tumors. Targeting of additional genes or gene families may lead to effective therapies for other malignancies.

4. On the origin of chromosomal abnormalities in human cancers

Although specific numerical and/or structural cytogenetic alterations have been associated with particular malignancies, the mechanisms by which those abnormalities occur have yet to be delineated.

Numerical chromosomal alterations can arise by random loss or gain of chromosomes, but also as a result of defects in the process by which equal numbers of chromosomes are distributed to daughter cells at mitosis, that is, chromosome segregation. Recent studies have shown that several factors can result in segregation defects, including abnormal kinetochore-spindle interactions, premature chromatid separation, centrosome amplification, multipolar spindles, and abnormal cytokinesis. Research by a number of investigators has recently advanced our understanding of the relationship between centrosomal defects, multipolar spindles, unequal chromosome distribution, and chromosomal instability. Investigations of several centrosomal proteins have been important in our understanding of segregational defects in human cells. Examination of Aurora A kinase and other proteins

Figure 3 Karyotype from a young boy with acute lymphoblastic leukemia. This translocation results in fusion of the *MLL* gene at 11q23 and the *MLL2/AF4* gene at 4q21, resulting in an abnormal chimeric transcript. The leukemia in these patients usually has aggressive clinical features, hyperleukocytosis, a B-precursor immunophenotype with coexpression of myeloid markers, and a poor response to conventional chemotherapy. 46,XY,t(4;11)(q21;q23). The derivative chromosomes 4 and 11 are marked by arrows

(pericentrin, NuMA, γ-tubulin, and polo kinase) involved in centrosome function and the spindle checkpoint are in progress (reviewed in Gollin, 2004). Their role in chromosomal instability and implications in the diagnosis, prognosis, and therapy of human tumors will be revealed in the coming years. Further, these proteins are candidate targets for drug development.

Structural aberrations in cancer cells include structural chromosomal alterations, including reciprocal and nonreciprocal translocations, homogeneously staining regions, amplifications, and deletions. The etiology of structural chromosomal abnormalities is not clear. However, we do know that (1) environmental agents, such as cigarette smoking, benzene, and other chemicals, cause DNA double-strand breaks; (2) repeated sequences, including duplicons and other genomic repeats may play a role in chromosomal rearrangements in cancer (Saglio *et al*., 2002; Lupski, 2003; and discussed in Rowley, 2001); and (3) patients with DNA repair defects are prone to develop cancer (Shiloh, 2003; Gollin, 2004). Thus, structural abnormalities in cancer may be related to one or a combination of factors, including the formation of DNA double strand breaks, and then either recombination between homologous genomic motifs and/or defects in the DNA damage response. Structural chromosomal abnormalities in cancer cells often result

Figure 4 Karyotype from a male with anaplastic large cell lymphoma with the t(2;5)(p23;q35) and trisomy 7. This translocation results in fusion between the anaplastic lymphoma kinase (*ALK*) gene on 2p23 and the nucleophosmin (*NPM*) gene on 5q35. 47,XY,t(2;5)(p23;q35),+7. The derivative chromosomes 2 and 5 are marked by arrows

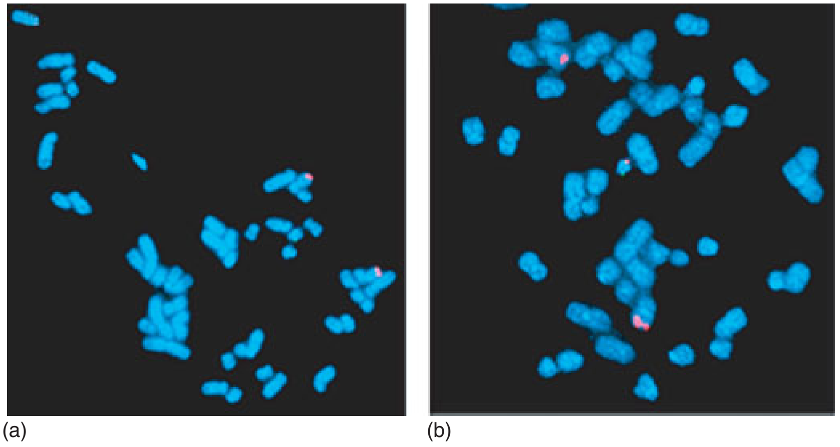

Figure 5 FISH for the *BCR/ABL* rearrangement, usually seen in chronic myelogenous leukemia. The cells are hybridized with the LSI *BCR/ABL* ES (extra signal) probe (Vysis, Inc., Downers Grove, IL). (a) Negative control (no rearrangement). Two red signals for the *ABL* oncogene (9q34) on distal 9q. Two green signals for the *BCR* gene at 22q11.2. (b) Metaphase from a CML patient with the t(9;22)(q34;q11.2). *BCR/ABL* rearrangement (adjacent red and green signals on the small Philadelphia chromosome in the center of the metaphase spread), one red signal on the normal chromosome 9, a residual red signal on the rearranged chromosome 9, and one green signal on the normal chromosome 22

in further structural alterations and instability due to chromosomal breakage. Factors involved in structural and numerical chromosomal instability in cancer cells are reviewed in more detail in Gollin (2004). Further studies on the mechanisms behind chromosomal alterations in human tumors are underway in many labs around the world.

5. Conclusion

Cancer cytogenetics has become a very important area of clinical cytogenetics, critical to the diagnosis of hematologic malignancies and helpful in the differential diagnosis of solid tumors. Research in cancer cytogenetics will continue to play an important role in the identification of oncogenes and tumor suppressor genes and examination of their function(s) in the cellular regulatory and signaling pathways. With the results of the Human Genome Project and the advances in molecular biology laboratory methodology and drug development, our prospects for significant advances in cancer diagnostic and prognostic testing and therapy based on the results of cancer cytogenetic studies are great. Yet, it is likely that classical as well as molecular cytogenetic studies will continue to be carried out on malignancies, as they provide a relatively rapid, inexpensive overall view of genomic alterations in a malignancy, useful for diagnosis, prognosis, and choice of therapeutic regimen.

Acknowledgments

The author is grateful to Ms. Maureen Sherer for preparing the illustrations for this contribution, Drs. Janet Rowley and Sofia Shekhter-Levin for helpful discussions, and the National Institute for Dental Research for continued research support. This article is dedicated to Professor Robert C. King on the occasion of his 75th birthday. He believed that the author could become a successful scientist and writer, and it happened because of his nurturing.

Specialist Review

Human X chromosome inactivation

Samuel C. Chang and Carolyn J. Brown
University of British Columbia, Vancouver, BC, Canada

1. X chromosome inactivation

1.1. The mammalian sex chromosomes

Dioecy, the presence of two distinct sexes, is common amongst animals. In mammals, sex determination is controlled by distinct sex chromosomes (the X and Y), which are believed to have originated from an autosomal chromosome pair by the acquisition of a major sex-determining locus and subsequent divergence (Ayling and Griffin, 2002). Suppression of recombination near the sex-determining locus would be evolutionarily favored; however, the absence of exchange between the homologs would also lead to the degeneration of the sex-determining Y over evolutionary time (Ohno, 1967). The human X and Y maintain identity in only a small region of homology at the tips of both the long and short arms, referred to as the "pseudoautosomal" region (PAR), which undergoes recombination during male meiosis. The male-specific region of the Y also retains 20 genes or gene families derived from X chromosomal sequences in addition to testis-specific multicopy sequences, many of which are arrayed in palindromic segmental duplications (Skaletsky *et al*., 2003). The presence of such repeats has been proposed as a mechanism allowing gene conversion to protect haploid Y genes against their inevitable decay due to acquisition of mutations (Rozen *et al*., 2003). The X retains much of its old autosomal information, including numerous important housekeeping genes, despite being a relatively gene-poor chromosome containing approximately 5% of the haploid genome but only about 3% of the genes (Graves *et al*., 2002).

1.2. Dosage compensation in mammals and other species

In response to the degeneration of the Y, there would have been adaptive pressure to increase expression from the single expressed X-linked copy of genes. Indeed, dosage of X-linked genes, despite their monoallelic expression, seems comparable to autosomal genes, as determined by comparison of expression levels of a variably X-linked gene in different species (Adler *et al*., 1997), microarray analysis (Disteche *et al*., 2001), or impact of aneuploidy (Mizuno *et al*., 2002). In addition,

excessive X-linked gene expression in females relative to males established the need for dosage compensation, which is achieved by X chromosome inactivation, whereby a single X is inactivated in female cells early in mammalian development. In individuals with an abnormal number of X's (e.g., 45,X; 47,XXX; 47,XXY, etc.), a single X remains active no matter how many are present (the "n−1" rule). In triploids, two X's can be active, implicating autosomal copy number in determining the number of X's that remain active (Migeon, 2002).

Dosage compensation also occurs in other dioecous organisms, utilizing a variety of mechanisms. In the fruit fly, *Drosophila melanogaster* (males XY, females XX), hypertranscription of most genes along the single male X matches the output of the female's two X's, and in the nematode, *Caenorhabditis elegans* (males XO, hermaphrodites XX), dosage compensation is accomplished in hermaphrodites by downregulation of X-linked gene transcription from both X's (reviewed in Marin *et al*., 2000). In birds (males ZZ, females ZW), there is some evidence for dosage compensation; however, it appears that this is not accomplished by the silencing of one Z chromosome as biallelic expression in the male is observed (Kuroiwa *et al*., 2002). Despite their substantial differences, dosage compensation in mammals, flies, and worms is thought to involve the control of chromatin structure, and in flies and mammals, it apparently involves functional RNAs (XIST in mammals, see below; and roX in flies (Meller *et al*., 1997; *see also* Article 27, **Noncoding RNAs in mammals**, Volume 3)). Mammalian X chromosome inactivation is unique amongst these mechanisms in that it requires differentiation between an active and inactive X within the same nuclear environment.

2. Features of the inactive X

The inactive X (Xi), as befits facultative heterochromatin, shares general features with constitutive heterochromatin. These include suppression of gene expression, condensation of chromatin (forming the Barr body), late replication, nuclease insensitivity, hypoacetylation of histones, and hypermethylation of DNA. However, several unique features characterize heterochromatin of the Xi, including the association of a large untranslated RNA, the X-inactive specific transcript (*XIST* in human or *Xist* in mice), and a nonrandom distribution of variants of the core histone H2A. Once the inactive state is established, silencing is faithfully maintained throughout subsequent mitotic cell divisions, resulting in clonal populations, that, in the case of some tumors, could include 10^9 cells (Linder and Gartler, 1965). Thus, X inactivation is a paradigm for both the establishment of a differentiated chromatin configuration and cellular memory of that differentiated state. Figure 1 summarizes some of these features of the Xi, which are discussed below.

2.1. *Gene silencing*

Genes that continue to be shared between the X and Y, notably those in the PARs, would have no need for dosage compensation, as they would continue to

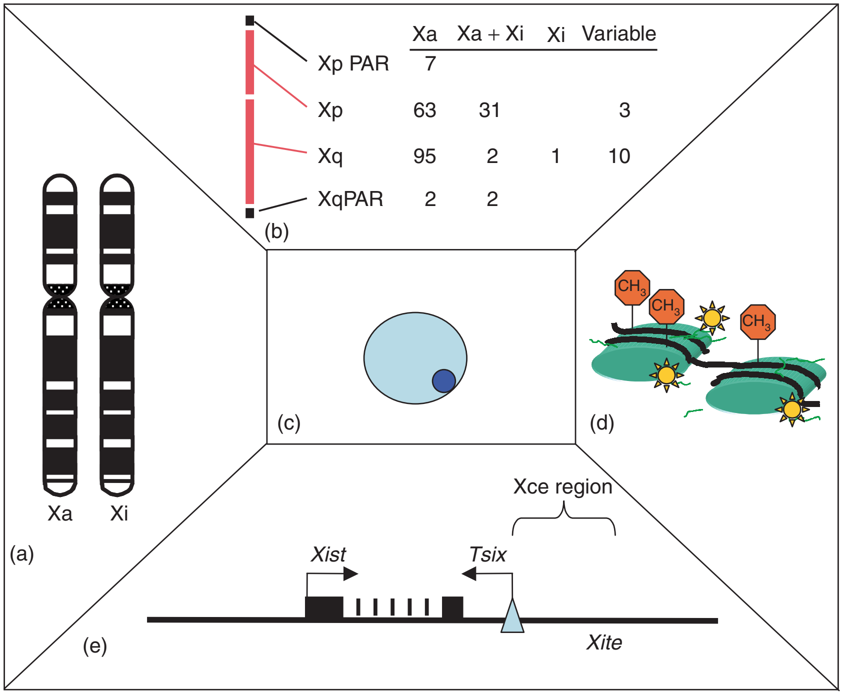

Figure 1 Facets of X inactivation. (a) In mammals, dosage compensation must differentiate between the active and inactive X chromosome in the same nuclear environment. Shown here are ideograms of the human X chromosomes. (b) Furthermore, in humans, approximately 15% of genes escape inactivation, being expressed from the Xa and Xi. As tabulated in this drawing, the majority of genes escaping inactivation are located on the short arm of the X (data from Carrel L, Cottle AA, Goglin KC and Willard HF (1999) *Proceedings of the National Academy of Sciences of the United States of America*, **96**, 14440–14444). (c) In interphase nuclei, the Xi can manifest as the Barr body, which stains darkly with DAPI, as diagrammed in this cartoon. (d) Modifications of the chromatin on the Xi include methylation of the DNA at the promoters of X-linked genes (shown as red stop signs) and hypoacetylation of histones as well as hypermethylation at lysine 9 and 27 of histone H3 (represented as stars). (e) The *Xist* gene is necessary for the establishment of inactivation, and in mice, *Xist* expression is regulated by the antisense *Tsix* transcript that initiates transcription at a CpG island (blue triangle) shown to bind CTCF. The choice of X to inactivate is influenced by the *Xce* locus and the recently defined *Xite* region (see text for references)

be present in two copies in both males and females, and thus it was anticipated that some genes would "escape" inactivation and continue to be expressed from the Xi (Lyon, 1962). What is surprising, however, is the number of genes escaping inactivation in humans. Over 15% of human genes continue to be expressed from the inactive X chromosome (Carrel *et al*., 1999), and clearly, not all of these have Y homologs. Thus, a dosage imbalance may continue to exist, whereby human females express more X-linked gene product than males. Interestingly, in mice, fewer genes have been identified to escape inactivation (reviewed in Disteche *et al*., 2002). Genes that escape inactivation are not all "fully" expressed from the Xi, and several human genes have been shown to have variable inactivation, escaping inactivation in some females but not in others (e.g., *TIMP1* and *CHM1* (Anderson

and Brown, 1999; Carrel and Willard, 1999)). The question of how some genes on the chromosome continue to be expressed while others are being silenced by a cis-acting mechanism is a fascinating biological question, and may also have clinical implications for disease, as discussed below. For many of the genes that have been examined, the general features of silent chromatin (e.g., replication timing, DNA methylation, and histone modifications) are not associated with an active gene on the Xi (see Disteche *et al*., 2002 for a review). A clue to the mechanism by which genes escape silencing may lie in the fact that many, although not all, of the genes expressed from the Xi are located in clusters, implicating a regional mechanism in their failure to be silenced (e.g. Tsuchiya and Willard, 2000). It is not clear whether expression from the Xi results from an initial inability to undergo inactivation or instead reflects an inability to maintain the silent state. The mouse *Smcx* gene is subject to inactivation in a proportion of embryonic cells; however, reactivation of the gene occurs very early in development (Lingenfelter *et al*., 1998). Such an early reactivation could be difficult to distinguish from the failure of inactivation spreading. Given the large number of genes escaping inactivation in humans, it is likely that there is more than a single mechanism by which expression from the Xi is acquired.

2.2. Barr body formation

During interphase, the human Xi forms a darkly staining body, the Barr body, which is seen associated with the nucleolus (Barr and Bertram, 1949) or at the nuclear periphery (Dyer *et al*., 1989), the usual sites for heterochromatin. Three-dimensional reconstructions of the Xi territory suggest that rather than being substantially more condensed than the active X (Xa), the principal difference between the two chromosomes is in shape (Eils *et al*., 1996). Thus, the intense staining of the Barr body with DNA dyes likely reflects the distinctive packaging of DNA on the Xi; however, to date, only a limited number of proteins have been shown to associate specifically with the Xi.

The Xi is characterized by the accumulation of variant histone H2A isoforms termed *macrohistone H2A1 and 2* (Costanzi and Pehrson, 1998; Chadwick and Willard, 2001). These proteins are very similar to H2A, but include a large carboxy-terminal domain, and their enrichment at the Xi forms a characteristic structure in the female nucleus, referred to as a *macrochromatin body* (*MCB*). MacroH2A has been shown to have a transcriptional repressive effect (Perche *et al*., 2000), potentially caused by both interfering with transcription factor binding and chromatin remodeling (Angelov *et al*., 2003). Deletion of *Xist* after inactivation results in loss of macroH2A association with the Xi (Csankovszki *et al*., 1999), while induction of *Xist* is sufficient to induce MCB formation (Rasmussen *et al*., 2001), suggesting a direct or indirect association between the Xist RNA and macroH2A. Such an association is further supported by coimmunoprecipitation of Xist by macroH2A antisera (Gilbert *et al*., 2000).

Chadwick and Willard (2003b) recently examined a variety of chromatin proteins for enrichment on the Xi and demonstrated elevated levels of heterochromatin protein-1 (HP1), histone H1, and the high mobility group protein HMG-I/Y at

the territory of the Xi in interphase human cells. The association, or at least the visualization of the association, of these various proteins with the Xi seems to be cell-cycle and perhaps cell-type specific, and often correlates with visualization of the Barr body (Chadwick and Willard, 2003a). Surprisingly, another protein shown to be associated with the inactive X and required for XIST localization is the BRCA1 protein (Ganesan *et al*., 2002), which has multiple cellular functions, including chromatin remodeling (Bochar *et al*., 2000). Furthermore, transient association of the polycomb group complex proteins Eed and Enx1 is seen in the earliest stages of X inactivation (Wang *et al*., 2001; Mak *et al*., 2002; Silva *et al*., 2003). Interestingly, these proteins are also required early in development for the monoallelic expression of some imprinted loci (Mager *et al*., 2003). Monoallelically expressed genes (both imprinted and X-linked) seem to have dimethylation of histone H3 at lysine (K) 4 restricted to the promoter and not the body of the gene, a mark that is already present in totipotent embryonic stem (ES) cells (Rougeulle *et al*., 2003). Intriguingly, this mark is not seen for the *Smcx* gene that shows rapid reactivation from the Xi.

2.3. Replication timing

Synchrony of replication origin firing in mammalian cells results in megabase-sized domains that replicate at a similar time during S phase (see Goren and Cedar, 2003 for a review). In general, expressed genes tend to replicate earlier in S phase than silenced genes (Woodfine *et al*., 2004). Late replication of the Xi is observed after pulse labeling of cells with bromodeoxy-uridine, and while there is some cell and tissue specificity to the replication patterns (e.g., Willard, 1977), there are regions of the inactive X that replicate earlier than the rest of the chromosome (e.g., XpPAR), and thus have been hypothesized to contain genes that do not undergo inactivation (Schempp and Meer, 1983). Assessment of replication timing for individual genes supports this suggestion as genes escaping inactivation show synchronous DNA replication between the Xa and Xi (e.g., Boggs and Chinault, 1994; Hansen *et al*., 1996). The origins of replication for the *HPRT* and *G6PD* loci are the same on the Xa and Xi (Cohen *et al*., 2003), implicating the yet-to-be-elucidated epigenetic determinants that delay replication firing on the Xi. A long-standing question is whether replication timing dictates the structure of chromatin or vice versa, and recent DNA injection experiments suggest that timing of replication is sufficient to alter transcriptional activity (Zhang *et al*., 2002). However, the transition from synchronous to asynchronous replication of the two X's in early embryos appears to follow alterations in histone modifications, suggesting that chromatin changes may establish the late replication of the Xi (Chaumeil *et al*., 2002).

2.4. Histone modifications

In addition to variants of the core histones, chromatin can vary in the modifications of histones (*see* Article 27, **The histone code and epigenetic inheritance**, Volume 1). Many amino acid residues of core histones, located predominantly within

the tail regions, have the potential to acquire a range of covalent modifications, including acetylation, methylation, ubiquitinylation, and phosphorylation. It has been hypothesized that a specific combination of modifications confers a particular property to the local chromatin, referred to as the "histone code" (Jenuwein and Allis, 2001), and the Xi shows modifications common to other regions of heterochromatin. Specifically, the Xi shows hypomethylation at K4 and 36, and arginine (R) 17 of histone H3; hypermethylation at K9 and K27 of histone H3; hypoacetylation at R2, R12, and R26 of histone H3 and K5, K8, K12, and K16 of histone H4 (see Chaumeil *et al*., 2002; Chadwick and Willard, 2003a). How the histone modifications associated with the Xi determine or influence interactions with other chromatin proteins that are involved in X inactivation is largely unknown, however, acquisition of H3 modifications is one of the first detectable events after Xist RNA coating of the presumptive Xi (Chaumeil *et al*., 2002). The Suv39h histone methyltransferase responsible for constitutive heterochromatin histone K9 methylation does not seem to be necessary for Xi histone methylation (Peters *et al*., 2002), while the Eed-Enx1 histone methyltransferase complex shows only a transient association with the Xi (Silva *et al*., 2003), implicating the involvement of additional chromatin-modifying enzymes in X inactivation.

2.5. *DNA methylation*

In mammals, symmetrical DNA methylation at CpG dinucleotides is a stable and clonally heritable epigenetic modification that is maintained by the action of a maintenance methyltransferase acting preferentially on hemimethylated substrates that result from DNA replication (Riggs, 1975). DNMT1 is generally ascribed this maintenance methylase activity, while DNMT3A and B are considered de novo methylases; however, understanding of how methylation patterns are established is limited (see Meehan, 2003 for a review). DNA methylation can regulate gene expression either by directly blocking transcription regulatory factors from binding to their target sequences or through several methyl-CpG-binding proteins that "read" DNA methylation patterns and form complexes with transcriptional repressor proteins including histone-modifying enzymes (Jones *et al*., 1998; Fuks *et al*., 2003). The CpG islands in the promoter regions of X-linked genes are heavily methylated on the Xi, in contrast to their unmethylated state on the Xa and the general state for autosomal genes. This epigenetic modification is one of the latest to be acquired during the process of X inactivation, following inactivation by several days and implicating methylation in maintenance rather than initiation of X-linked gene silencing (Keohane *et al*., 1996). X inactivation in marsupials and eutherian extraembryonic tissues, where there is reduced DNA methylation, is less stable (e.g., Kaslow and Migeon, 1987; Migeon *et al*., 1985). Similarly, patients with immunodeficiency-centromeric instability-facial anomalies syndrome (ICF, MIM 242860), which results from mutations in *DNMT3b*, have some hypomethylated CpG islands, and show reactivation of some X-linked loci in some cells (Hansen *et al*., 2000). Interestingly, they also show hypomethylation of LINE elements on only the Xi, suggesting that another methyltransferase is involved in LINE element methylation on the Xa and autosomes (Hansen, 2003). Furthermore, inhibition or

loss of DNA methyltransferase leads to derepression of X-linked genes, providing experimental evidence for the importance of DNA methylation in maintenance of X inactivation (Venolia *et al*., 1982; Sado *et al*., 2000). Synergism between XIST localization, DNA methylation, and histone modifications results in extremely stable silencing of the Xi (Csankovszki *et al*., 2001).

3. Process of inactivation

X inactivation can be envisioned as a cycle of events. Reactivation of the entire Xi occurs normally during oogenesis, while the X chromosome is transcriptionally inactivated together with the Y chromosome in spermatogenic cells shortly before or during early meiotic prophase. Such male meiotic sex chromosome inactivation (MSCI) has been suggested to mask the nonsynapsed regions of the sex chromosomes, possibly in order to avoid the checkpoint that causes germ cell death in response to defective chromosome synapsis; prevent the initiation of recombination events in the nonsynapsed regions of the sex chromosomes; or ensure efficient sex chromosome synapsis (reviewed in Turner *et al*., 2002). Inactivation occurs in female somatic cells at approximately the time of implantation during the late blastula stage, and is observed first in the extraembryonic tissues, where it is imprinted in mice (see below, and Article 41, **Initiation of X-chromosome inactivation**, Volume 1). Recent results suggest that the mouse X may be partially inactivated at the 2-cell stage (Huynh and Lee, 2003), and that early imprinted silencing is reversed in cells of the inner cell mass prior to random inactivation (Okamoto *et al*., 2003). As human X inactivation is not imprinted, it is not known to what extent events in very early development will be similar between humans and mice.

Much of our current understanding about the molecular mechanisms involved in the regulation of X inactivation is derived from the studies of mice, particularly ES cells that can undergo inactivation upon differentiation. A time line of inactivation suggests that first XIST expression is stabilized, coating the future Xi, and then histone modifications, gene silencing, asynchronous replication, and macroH2A accumulations occur (Chaumeil *et al*., 2002). The mechanism by which inactivation spreads in cis along the 160-megabase chromosome remains unsolved (*see* Article 40, **Spreading of X-chromosome inactivation**, Volume 1); however, it has been hypothesized that there are “way-stations” or booster elements distributed along the chromosome that serve to assist in the propagation of inactivation (Riggs *et al*., 1985). In X/autosome translocations, silencing can spread into the autosomal region; however, spread within the autosome does not seem to be as effective as on the X (White *et al*., 1998). Thus, way-stations are likely concentrated on the X, and Lyon has hypothesized that LI elements, which are enriched on the X, could be the way-stations (Lyon, 1998). Several bioinformatic studies have examined the characteristics of regions that escape inactivation (Bailey *et al*., 2000; Friel *et al*., 2002). However, as mentioned above, such regions may escape inactivation either because of failure to respond to the initial signal or inability to maintain silencing; and thus, the enrichment of particular elements

in these regions may reflect a role in either the spread or the maintenance of silencing.

3.1. The X inactivation center

A critical region necessary for inactivation of the X was defined by the analysis of the ability of rearranged X's to undergo inactivation. This region, the X inactivation center (*XIC*), was refined to 1 Mb of human Xq13 (Leppig *et al*., 1993), and more recent mouse transgenic studies suggest that the *Xic* is no more than 450-kb long (Lee *et al*., 1996). This region includes the *XIST/Xist* locus, as well as several cis-acting loci that influence the random choice of X to inactivate (reviewed in Rougeulle and Avner, 2003; and discussed below).

3.1.1. XIST

XIST/Xist, a large (>15 kb) alternatively processed, noncoding RNA, is the only gene known to be transcribed from the Xi but not from the Xa in somatic cells, and the RNA associates in cis with the Xi as part of the Barr body (Brown *et al*., 1991; Brockdorff *et al*., 1991; Clemson *et al*., 1996). The *Xist* gene is required for inactivation, and transgenes of *Xist* are able to induce inactivation of autosomes, identifying *Xist* as the principal component of the *Xic* (see Rougeulle and Avner, 2003). Prior to the onset of inactivation, *Xist* is unstable and expressed at a low level from all X chromosomes. Upon differentiation, *Xist* RNA is stabilized and coats the presumptive Xi, while the low-level pinpoint of *Xist* RNA on the Xa is subsequently extinguished (Panning *et al*., 1997; Sheardown *et al*., 1997).

Xist is known to be essential for the initiation of X inactivation based on targeted deletions in the mouse. Specifically, an *Xist* deficiency in female ES cells abolishes X inactivation potential in cis, enabling inactivation only of the chromosome carrying the wild-type *Xist* allele. Subsequent experiments have suggested that the *Xist* RNA levels determine which X undergoes inactivation (Nesterova *et al*., 2003). The continued expression and association of the transcripts with the Xi in somatic cells also implicated the RNA in the maintenance of the Xi; however, deletion of *XIST/Xist* after inactivation does not eliminate gene silencing (Brown and Willard, 1994; Rack *et al*., 1994; Csankovszki *et al*., 1999), although it does eliminate macroH2A association and increases the rate of reactivation of individual genes (Csankovszki *et al*., 2001). Reactivation in the absence of *Xist* is synergistically enhanced by treatment with demethylating or deacetylase-blocking agents, emphasizing the highly redundant nature of the maintenance of inactivation (Csankovszki *et al*., 2001).

Xist by itself, however, is not sufficient to induce chromosome-wide gene silencing in rodent somatic cells where reactivation of the endogenous *Xist* or induction of Xist-encoding transgenes produce localized Xist that does not inactivate the X (Clemson *et al*., 1998; Hansen *et al*., 1998; Rasmussen *et al*., 2001). Nevertheless, in human-transformed cells, it has been demonstrated that *XIST* expression can induce hallmarks of silencing, suggesting that the ability of *XIST/Xist* to induce inactivation may be species or cell-type specific (Hall *et al*.,

2002). Unexpectedly, in human/mouse hybrid cells, *XIST* is unable to localize to the human X, implicating species-specific factors in the chromatin recognition of *XIST* (Clemson *et al*., 1998; Hansen *et al*., 1998).

Xist RNA consists of separable domains for silencing and coating the chromosome in cis (Wutz *et al*., 2002). The transcriptional silencing activity of the transcript can be attributed to a domain at the 5′ end of the RNA that shows sequence conservation in all species in which *Xist* has been analyzed. An *Xist* RNA deleted for this 5′ domain coats, but does not silence, the X. Furthermore, only RNAs that were capable of coating the chromosome were functional in silencing. The separable motifs within *Xist* RNA probably recruit protein complexes to mediate coating and/or silencing of the X.

3.1.2. Tsix

A gene overlapping and antisense to *Xist*, named *Tsix*, has been identified in mouse ES cells; it is expressed from both X's before and during, but not after, differentiation (Lee *et al*., 1999; Debrand *et al*., 1999). *Tsix* initiates at a major transcription start site 13 kb downstream of the *Xist* 3′ end and includes four exons that undergo alternative splicing (Mise *et al*., 1999; Shibata and Lee, 2003). Like *Xist*, *Tsix* has no open reading frames, and its RNA is found in the nucleus. *Tsix* expression seems opposed to *Xist* expression, and truncation of the *Tsix* transcript led to complete nonrandom inactivation of the targeted X chromosome (Luikenhuis *et al*., 2001). Induction of *Tsix* transcription during ES cell differentiation, on the other hand, caused the targeted chromosome always to be chosen as the active chromosome (Stavropoulos *et al*., 2001). These results suggest that *Tsix* is a critical negative regulator of *Xist*. *Tsix* knockout mice show a dramatic parent-of-origin phenotype consistent with *Tsix* being a central player in imprinted inactivation (Lee, 2000). Although an antisense reminiscent of *Tsix* has been reported in humans, the roles of the human *TSIX* remain controversial (Migeon *et al*., 2001; Chow *et al*., 2003).

3.1.3. Xce and random versus imprinted X chromosome inactivation

In eutherian embryonic cells, the choice between inactivation of the maternally or paternally derived X is random. However, in marsupials, the paternal X is inactivated in all cells (Cooper *et al*., 1971), and a similar imprinted inactivation is found in the extraembryonic tissues of mice in which the paternal X is always inactive (Takagi and Sasaki, 1975). *Tsix* has been suggested to be the cis-acting imprinting factor that protects the maternal X from silencing, thus playing a critical role in imprinted X inactivation within developing mouse extraembryonic tissues (Lee, 2000; Sado *et al*., 2001). Preferential paternal inactivation in the extraembryonic tissues is also observed in cows (Xue *et al*., 2002). While there have been some conflicting results, it appears that despite some limited bias toward paternal inactivation in early trophoblast, inactivation in the extraembryonic tissues of humans is not imprinted (see review by Migeon, 2002).

In mice, the X controlling element (*Xce*), biases inactivation toward one X, with 20–30% distortions from random inactivation being observed in mice with

different alleles of the *Xce* locus (Cattanach and Issacson, 1967). *Xce* maps 3′ to *Xist* (Simmler *et al*., 1993), and the *Xite* locus has been proposed as a candidate for *Xce* activity. *Xite* is a region of intergenic transcription beyond *Tsix* that is associated with DNaseI hypersensitivity (Ogawa and Lee, 2003). A human equivalent to *Xce* has not been identified, although a screen of 38 families identified several families with a statistically significant skewing of X inactivation (Naumova *et al*., 1998). Mutations in the *XIST* promoter have been associated with deviations in X inactivation, but this strong skewing of inactivation was not consistent throughout families (Plenge *et al*., 1997; Tomkins *et al*., 2002). A mutational screen for modifiers of the X inactivation ratio in mouse identified two autosomal dominant loci, which have yet to be characterized (Percec *et al*., 2002).

4. Clinical consequences and considerations

X inactivation results in mammalian females being mosaics, composed of cell lines in which either the maternally or the paternally inherited X is inactivated. This mosaicism is generally sufficient to protect females from X-linked disease, but females may show "patchy" expression if the gene product is cell restricted, or disease, depending upon the randomness of their X inactivation pattern. There are also X-linked dominant disorders, many of which are believed to be male lethal (e.g., Rett syndrome, MIM 312750 or incontinentia pigmenti, MIM 308300), although others seem to manifest predominantly in females, possibly due to metabolic interference (e.g., craniofrontonasal syndrome MIM 304110 (Wieland *et al*., 2002)).

The process of inactivation also minimizes the impact of X aneuploidy, as all but one X will be inactivated. However, the lack of an Xi in females results in Turner syndrome, demonstrating that the Xi provides critical gene products for normal development, which are presumably provided by the Y in males. Female mice lacking an Xi show less phenotypic consequence, likely reflecting the fact that fewer genes are expressed from the Xi in mice (Disteche *et al*., 2002). The X/Y homologous genes represent only a small proportion of the genes that are expressed from the Xi in humans (Carrel *et al*., 1999), and thus, there is the possibility for considerable differential expression between males and females. The role of differential X-linked gene expression is quite difficult to separate from the substantial hormone-induced differences between males and females; however, there is a developing literature supporting difference in sex-chromosome gene expression between the sexes, particularly in brain (e.g., Xu *et al*., 2002; Good *et al*., 2003).

Deviations from the normal random inactivation pattern can occur either owing to primary influences upon the choice of X to inactivate or more likely owing to postinactivation selection for or against a population of cells with one X active (Migeon, 1998). A large number of assays have been developed that combine an X-linked polymorphism with a distinguishable feature of the Xi or Xa (generally methylation or expression) to allow determination of the extent of skewing of inactivation. In addition to being used to determine skewing in females suspected of carrying X-linked defects, these assays are often used for the analysis of clonality

in tumor tissue. If a tumor originates from a single cell, tumor tissues will have the same inactivation pattern in all cells. This nonrandom pattern of inactivation has been observed in a wide range of neoplastic tissue, demonstrating the monoclonal origin of the neoplasia (reviewed in Busque and Gilliland, 1998).

Although the analysis of inactivation patterns in females has been valuable in studies of carriers of X-linked disease and for determining the clonality of tumors, our limited understanding of the contribution of different causes of skewing confounds the utility of such studies. Skewed inactivation patterns have been reported in association with females with breast cancer, ovarian cancer, or females with recurrent spontaneous abortions, and these associations have yet to be satisfactorily explained (Buller *et al*., 1999; Kristiansen *et al*., 2002; Sangha *et al*., 1999, Lanasa *et al*., 1999, Uehara *et al*., 2001). One possibility is that X-linked mutations underlie such associations (e.g., Lanasa *et al*., 2001). Alternatively, skewing of inactivation may reflect a limitation in the number of viable cells that contribute to an embryo, as is the case for the skewed inactivation frequently observed in fetuses or newborns associated with confined placental mosaicism, in which a trisomic conceptus likely underwent a rescue event leading to a limited population of disomic cells (Lau *et al*., 1997). Thus, further studies are necessary for the determination of the cause or causes of these associations.

Short Specialist Review

Nondisjunction

Neil E. Lamb
Emory University, Atlanta, GA, USA

Nondisjunction is the improper segregation of chromosomes during either meiotic or mitotic cell divisions. The result of nondisjunction is dosage imbalance – either one extra or one missing chromosome for some proportion of the resulting cells. Mitotic nondisjunction is commonly observed in cancer cells (*see* Article 14, **Acquired chromosome abnormalities: the cytogenetics of cancer**, Volume 1), while nondisjunction during meiosis results in gametes that are chromosomally unbalanced (*see* Article 11, **Human cytogenetics and human chromosome abnormalities**, Volume 1). If an unbalanced gamete participates in fertilization, the resulting embryo will be aneuploid, with either one chromosome too many (trisomy) or one chromosome too few (monosomy). Such embryos are generally inviable, and for humans, this has serious clinical consequences. As the most commonly identified chromosome abnormality, identified in at least 5% of all clinically recognized pregnancies, aneuploidy is the leading known cause of pregnancy loss and fetal wastage. Among conceptions that survive to term (primarily trisomy for chromosomes 13, 18, and 21 and various combinations of the sex chromosomes), aneuploidy is the leading genetic cause of mental impairment and developmental disabilities.

Unlike humans, nondisjunction in most organisms is a very rare occurrence. For example, chromosome missegregation is estimated to occur in only 1 of every 10 000 meiotic events for *Saccharomyces cerevisiae* (Sears *et al*., 1992). The underlying basis for the increased incidence in humans is unclear as the basic meiotic pathway is highly conserved across species. Meiosis generates haploid gametes through a process that consists of one round of DNA replication followed by two cellular divisions (*see* Article 13, **Meiosis and meiotic errors**, Volume 1). The first cell division (known as *meiosis I* or *MI*) separates homologous chromosomes (Figure 1), while meiosis II (MII) segregates the sister chromatids of each homolog. Nondisjunction can occur at either of these meiotic divisions, and the alternatives can often be distinguished using polymorphic genetic markers at or near the centromere of the nondisjoined chromosome. If both copies of the nondisjoined chromosome are heterozygous for alleles at these markers, it is likely that the error arose at MI. In contrast, homozygosity at the centromere of the nondisjoined chromosomes suggests an error at MII. In much the same way, marker studies can be used to determine in which parent the nondisjunction error occurred. As a result, numerous aneuploid conditions have been studied to

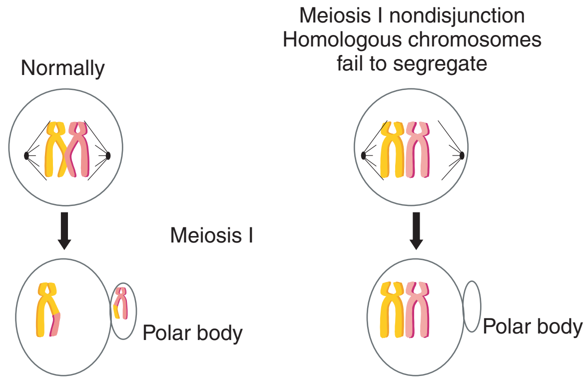

Figure 1 During the first stage of meiosis, homologous chromosomes segregate, traveling to opposite poles of the spindle. In humans, one homolog is placed in the polar body, while the other remains in the maturing oocyte. Nondisjunction at the first meiotic division results in both homologs traveling toward the same spindle pole. This is frequently associated with altered patterns of meiotic recombination along the nondisjoined homologs: generally either poor positioning of existing recombination or a lack of recombination altogether

determine the parental origin and meiotic stage of the nondisjunction error. Very little data has been identified for monosomic conditions, which appear to result in early embryonic lethality. In contrast, most trisomic conditions are compatible with at least some fetal development and results are available for several trisomies (reviewed in Hassold and Hunt, 2001). These data show remarkable variation with respect to parental origin and meiotic stage. Nonetheless, it is evident that maternal meiosis I nondisjunction errors predominate among nearly all trisomic conditions. This is perhaps not surprising, given that the first stage of meiosis in females is amazingly protracted: it is initiated prenatally in all oocytes but arrested shortly thereafter and is not resumed until just before the oocyte is ovulated, 15 to 50 years later. In addition, increasing evidence suggests that meiotic disturbances are handled differently between males and females (reviewed in Hunt and Hassold, 2002). Abnormalities that often lead to prophase or metaphase–anaphase arrest in male meiosis appear to escape detection in female meiosis, leading to nondisjunction. Consequently, it is clear that an understanding of the risk factors for human aneuploidy will require a greater understanding of the events of meiosis I in the human female.

Despite the high frequency and obvious clinical importance of nondisjunction, there is a lack of knowledge about the predisposing genetic and environmental factors. However, there is one factor incontrovertibly linked to human aneuploidy – increasing maternal age. Most, if not all, human trisomies are affected by increasing maternal age, although the magnitude of the effect varies among trisomies (Risch *et al*., 1986; Morton *et al*., 1988). Among women under the age of 25 years, ~2% of all clinically recognized pregnancies are trisomic but this frequency approaches 35% for women over the age of 40. Very little is understood regarding the mechanisms that underlie this age effect. It is thought to involve meiosis I, consistent with the studies described above examining the parent and meiotic stage

of the nondisjunction event. However, the specific timing of the event is unclear, and numerous models have been advanced to describe when in meiosis I the age effect develops (for review see Gaulden, 1992).

Recently, altered genetic recombination has been identified as the first molecular correlate of human nondisjunction. In model organisms, mutations that affect the amount and location of meiotic recombination are associated with nondisjunction. It appears that altered amounts and placement of recombination in humans also increases the risk for nondisjunction. It is possible to recapitulate the recombination patterns that occurred in meiotic events that ultimately lead to nondisjunction. Studies of this type have identified significant reductions in recombination for all meiosis I trisomies studied to date, including maternally derived cases of trisomies 15, 16, 18, 21, and sex-chromosome trisomies (Hassold *et al*., 1995; Lamb *et al*., 1996, 1997; Bugge, 1998; Robinson, 1998). Reduced recombination has also been identified in paternally derived cases of trisomy 21 and Klinefelter syndrome (47, XXY) (Savage, 1998; Thomas, 2000). For many of these trisomies, the reduction in recombination has been due to a proportion of cases that never engaged in genetic recombination. In addition, altered placement of meiotic recombination has been identified for a subset of maternally derived trisomies 21 and 16, with the exchange events occurring more distal than expected. These "distal only" exchange events appear to be less efficient at proper chromosome segregation.

Surprisingly, altered patterns of meiotic recombination are also associated with maternal meiosis II trisomy for chromosome 21 (Lamb, 1997). Specifically, the increase was most pronounced in the pericentromeric region of the chromosome. The connection between recombination (a meiosis I event) and the meiosis II nondisjunction may be explained if the meiosis II errors actually originated in meiosis I by chromosome entanglement due to the pericentromeric exchange or premature separation of sister chromatids at meiosis I followed by comigration of the sister chromatids due to chance at meiosis II. As a result, the nondisjoined chromosomes would have identical centromeres, leading to the "meiosis II" classification even though the event was initiated at meiosis I. Subsequent studies of trisomy 18 or sex-chromosome trisomy arising at maternal meiosis II have not, however, identified a significant effect for recombination. As a result, it appears likely that the liability posed by altered recombination varies from chromosome to chromosome.

Do other risk factors exist for nondisjunction? When compared to the maternal age effect, additional proposed risks have a much weaker or unsubstantiated influence. Many such factors have been proposed, including: the effects of diminished oocyte pool leading to increased risk of nondisjunction and earlier maternal menopause (Kline, 2000); a reduced ovarian complement, due to the congenital absence or surgical removal (Freeman, 2000); maternal smoking and oral contraceptive use around the time of conception (Yang, 1999); and maternal polymorphisms at genes in the folate pathway (van der Put, 1998; Hobbs, 2000). In addition, various chemical, drug, or irradiation exposures have also been evaluated (Hook, 1992). To date, however, none of these potential risk factors have been conclusively proven. This does not mean that there are no relevant risk factors – possibly the impact is so small that each risk escapes detection. On the other hand, the correct risk factors may have simply not been identified. Regardless,

an understanding of the molecular mechanisms for nondisjunction and the maternal age effect remains elusive.

Short Specialist Review

Microdeletions

John A. Crolla
Wessex Regional Genetics Laboratory, Salisbury District Hospital, Salisbury, UK

In the 1980s, the development of in situ hybridization techniques, particularly those utilizing fluorescent markers (FISH) (*see* Article 22, **FISH**, Volume 1) (Pinkel *et al*., 1988), led to the discovery of the first cryptic deletion syndromes, that is, those in which the missing material was not visible using conventional microscopy. Discovery of most microdeletion syndromes resulted from collaborations between clinicians, cytogeneticists, and molecular geneticists. Chromosome markers such as translocation breakpoints found in patients with abnormal phenotypes were often pivotal in identifying the chromosomal region of interest following which positional cloning methods resulted in the identification and characterization of the gene(s) of interest (Tommerup, 1993). For example, the first direct evidence that hemizygosity at the *ELN* locus contributes to the Williams syndrome phenotype followed a report that a t(6;7)(p21.1;q11.23) translocation was segregating in a family with dominant supra valvular aortic stenosis (SVAS) (Ashkenas, 1996). Subsequent studies have identified a number of genes implicated in the William's contiguous gene phenotype, and in common with many other human microdeletion syndromes, hemizygosity at one or more loci leading to the disruption of expression of dosage-sensitive genes appears to be the principal mutational mechanism underlying the clinical phenotypes.

There have been over 60 reported microdeletion syndromes (*see* Article 87, **The microdeletion syndromes**, Volume 2) involving virtually all chromosomes (Table 1). Although haploinsufficiency of dosage-sensitive genes is thought to be the main mutational mechanism(s) underlying the associated clinical phenotype(s), there are rare examples where the deletion's breakpoints per se appear to be the mutational mechanism mediated by the breakpoint disrupting a regulatory element that controls a nearby gene (e.g, $3'$ interstitial deletions in cases with aniridia; Lauderdale *et al*., 2000; Crolla and van Heyningen, 2002).

Several terminal, or more correctly, subtelomeric deletions have been described following analysis of patients with normal karyotypes using chromosome-specific sub-telomere FISH probes (Knight *et al*., 1997). These studies were instrumental in defining the so-called terminal deletion syndromes that are distributed throughout the genome and were found in ~5% patients with idiopathic developmental delay with or without associated congenital abnormalities (de Vries *et al*., 2003). A proportion of the deletions observed in these studies were the unbalanced products

of balanced parental rearrangements (usually translocations), and reciprocal duplications have also been reported.

The molecular mechanisms underlying the formation of at least some of the cryptic rearrangements are being elucidated, some of which are thought to arise following unequal meiotic recombination mediated by the proximity of nonallelic segmental duplications particularly in the pericentromeric and telomeric regions (Emanuel and Shaikh, 2001). However, alternative mechanisms may operate. For example, the presence in some mothers with children with Angelman's syndrome and del(15)(q11-q13) of a submicroscopic heterozygous inversion at the regions defined by flanking segmental duplications has been proposed to represent "an intermediate estate" that facilitates the formation of a deletion in an offspring (Gimelli *et al*., 2003). Clearly, genomic organization has a pivotal role in determining the position and frequency of specific microdeletion syndromes and the several models proposed to date may not be exhaustive (Emanuel and Shaikh, 2001).

The discussion so far has focused on techniques used to identify imbalances at specific genomic locations. Leading up to the publication of the advanced draft assembly of the Human Genome Sequence in 2001, attention switched to the innovative use of fully sequenced clones (principally Bacterial or P1 Artificial Chromosomes, BAC/PACs). A method called "Array-CGH" was developed (*see* Article 55, **Polymorphic inversions, deletions, and duplications in gene mapping**, Volume 1) in which selected BAC/PAC clones (with an average insert size of ~150 Kb) were selected sequentially at contiguous genomic locations ~1 Mb apart and then spotted onto glass slides to act as targets for a comparative genomic hybridization (CGH) experiment using a probe mixture comprising differentially labeled DNA derived from both normal and clinically affected individuals (Fiegler *et al*., 2003). This approach opened up the possibility of detecting copy number changes either throughout the genome with a resolution only constrained by the density of the clones selected (i.e., at 1 Mb or complete coverage using tiling path clones (Ishkanian *et al*., 2004)) or at high density but focused on specific genomic regions.

A number of studies utilizing Array-CGH have illustrated the potential of this approach but has also provided unexpected insights into the number and distribution of large genomic imbalances distributed throughout the genome that may turn out to be nonpathogenic polymorphisms (see below). Array-CGH focused on specific chromosomal regions has been used to define critical deletion regions for specific phenotypes such as Congenital Aural Atresia in patients with 18q22.3-18q23 deletions (Veltman *et al*., 2003), 1p36 deletions (Yu *et al*., 2003), and imbalances involving 17p11-p12 (Shaw *et al*., 2004). Targeted Array-CGH led to the refinement of a critical deletion interval in 8q12 in some patients with CHARGE syndrome (a developmental disorder with a nonrandom pattern of congenital abnormalities). Sequence analysis of genes found in the deleted segment found mutations in *CHD7* in 10 out of 17 patients with CHARGE syndrome (Vissers *et al*., 2004), thereby illustrating the utility of Array-CGH for the identification of some novel disease-related gene loci.

Array-CGH has also been used in whole-genome scans using BACs at 1-Mb resolution on chromosomally normal patients with idiopathic developmental delay or mental retardation with and without associated congenital abnormalities. The

first studies reported similar results (Table 2). Shaw-Smith *et al*. (2004) and Vissers *et al*. (2003) used 1-Mb Array-CGH on similar patient groups and showed that ∼25% carried genomic imbalances, that is, deletions or duplications. One-third of these imbalances were subsequently found to be carried by a clinically normal parent and were considered to be polymorphic copy number changes. However, the remaining two-thirds were novel de novo microdeletions/duplications (*see* Article 52, **Algorithmic improvements in gene mapping**, Volume 1), which further studies will determine whether they are directly responsible for the clinical phenotypes observed.

Two subsequent papers reported large-scale copy number variations (deletions and duplications) ranging in size from 100 Kb to 2 Mb in two ethnically and geographically distinct populations of normal control individuals (Table 2). Iafrate *et al*. (2004), using Array-CGH, reported 255 variable loci in 55 individuals compared to Sebat *et al*. (2004) who used an oligonucleotide array and demonstrated 76 genomic changes in 20 individuals. Interpretation of what constitutes a pathogenic genomic imbalance compared to a polymorphism, particularly those involving microdeletions, will only be possible once the technical parameters, including the

Table 2 Number and distribution of large genomic imbalances in affected and control populations

Iafrate *et al*. (2004)	Array-CGH	55	>150	255 LCVs (ave: 6.5)	142 (55%)

choice and density of clones used in the array, as well as an understanding of the sequences involved in "common" imbalances are fully understood (Carter, 2004).

In conclusion, our understanding of the clinical effects and mutational mechanisms associated with genomic imbalances, particularly deletions, has come a long way since the first cytogenetic karyotype/phenotype correlations in the 1960s and the descriptions of the first microdeletion syndromes in the 1980s. The future development of high-density genomic arrays promises further insights into the complex structure of the "normal" human genome, from which novel microdeletion syndromes will emerge providing new diagnostic strategies and insights into disease-associated human gene(s).

Short Specialist Review

Mosaicism

Wendy P. Robinson
University of British Columbia, Vancouver, BC, Canada

1. Mosaicism-overview

Chromosome mosaicism, the existence of two cell lines with differing chromosomal constitutions derived from a single fertilization, may be observed in amniotic fluid (AF) or chorionic villus (CVS) samples at prenatal diagnosis or in blood or skin samples of individuals referred for a variety of medical conditions. The diagnosis of mosaicism, particularly when ascertained prenatally, presents one of the most problematic genetic counseling situations as it is impossible to fully assess the level and distribution of the abnormal cells or to predict whether outcome of the pregnancy will be normal or not. In cases of mosaicism ascertained postnatally, the abnormal cells may be diagnostic for a specific syndrome, for example, the finding of mosaic tetrasomy 12p in a child with profound mental retardation and other features of Pallister–Killian syndrome (Schinzel, 1991), but can also be inconsequential, for example, a low level of 45,X cells in a woman experiencing recurrent miscarriage (Horsman *et al*., 1987). The interpretation of a mosaic finding thus needs to be carefully considered in terms of the patient phenotype, the type and origin of the abnormality, and the extent of abnormal cells.

To appreciate the effects of mosaicism, it is first important to consider that all human beings are very likely mosaics. The replication of the cellular genome, while reasonably accurate, is not foolproof and mutations arise and chromosomes segregate improperly with some low probability at each mitotic cell division. How low? That depends on the cell type and the type of abnormality. Studies of unused human embryos from in vitro fertilization (IVF) procedures have indicated that at least 70% are chromosomally abnormal, many of which may show mosaicism with normal diploid cells (Gianaroli *et al*., 2001; Magli *et al*., 2001; Ruangvutilert *et al*., 2000; Wells and Delhanty, 2000). This Figure may well be close to 100% if all cells and all chromosomes could be examined at once. There is presumably a high rate of chromosome missegregation, as well as misdivision of whole haploid complements in the first few postzygotic cell divisions (at least under IVF conditions). Very high rates of chromosome aneuploidy have also been found in normal neurons of the developing and mature mouse brain (Kaushal *et al*., 2003) and tetraploid cells are common in placental trophoblast of many mammals (Hoffman and Wooding, 1993), suggesting that the production of chromosomally "abnormal" cells may be part of the normal programmed development of some cell types. Aneuploid cells are also

found at increasing frequency in cultured lymphocytes as individuals age. The X chromosome seems particularly susceptible to nondisjunction and, on average, about 2–3% of cultured lymphocytes in young women (Fitzgerald and McEwan, 1977; Horsman *et al*., 1987; Nowinski *et al*., 1990) and 22% in female centenarians (Bukvic *et al*., 2001) exhibit X chromosome aneuploidy.

Most embryos with a high percentage of abnormal cells probably do not survive implantation or are aborted in early pregnancy, but it is not known how often low-level mosaics are rescued by the plasticity of early development and go on to produce term births. Mosaicism is detected in 1–2% of CVS and 0.1% of AF samples, mostly involving a trisomic (47 chromosomes) cell line. The lower rate of mosaicism in AF samples reflects both the fact that some abnormal pregnancies will be lost between the time of CVS (8–12 weeks gestation) and amniocentesis (15–20 weeks gestation) and that mosaicism is more commonly found in the placenta as compared to the fetus. However, the true frequency of fetal mosaicism is presumably higher, as AF and fetal blood analysis have been shown in several instances to fail to detect a trisomy that is later found in the fetus or newborn (Bruyere *et al*., 1999; Désilets *et al*., 1996; Hammer *et al*., 1991; Opstal *et al*., 1998). Chromosomal mosaicism has been observed in as many as 5–15% of placentae examined from healthy term pregnancies when multiple placental sites were examined (Artan *et al*., 1995). While low levels of trisomic cells in the placenta probably have little impact (and may even be normal), high levels may impair placental function and thus impede fetal growth.

Pregnancy outcome in the case of mosaicism is often associated with how the mosaicism arose. Mosaicism may originate through gain/loss of a chromosome in a normal diploid conceptus (somatic origin) or the abnormal cell line may be present at conception (meiotic origin), but the error "corrects" itself by loss of the supernumerary chromosome during development (Figure 1). Not surprisingly, when the conceptus originates from an abnormal zygote, there tends to be higher levels of trisomy in the placenta, higher risk for fetal mosaicism, and the pregnancy is at higher risk of fetal growth restriction, malformation, and intrauterine or neonatal death (Robinson *et al*., 1997). Uniparental disomy (*see* Article 19, **Uniparental disomy**, Volume 1) (both copies of a chromosome pair originating from the same parent) of the normal cell line can also occur in such cases, which may have a significant phenotypic effect when imprinted genes are located along the involved chromosome. Nonetheless, in many cases, there is a selective advantage of the normal cell line, thus making it possible for a nonmosaic diploid fetus to result from an abnormal conception. For example, trisomy 16 mosaics virtually always derive from a trisomic zygote, but it has been inferred that it is possible to form a baby with entirely (or predominantly) normal cells from only a single diploid cell from the inner cell mass of the blastocyst (Lau *et al*., 1997; Robinson *et al*., 2002). While pregnancies with prenatally diagnosed trisomy 16 mosaicism are at increased risk of complications (poor growth, maternal hypertension, and fetal malformations) due to placental trisomy or low-level trisomy in the fetus, it is truly remarkable how often they proceed successfully. In fact, most cases of mosaicism, even when detected in AF cultures, will have a good prognosis (see e.g., Hsu *et al*., 1997; Wallerstein *et al*., 2000).

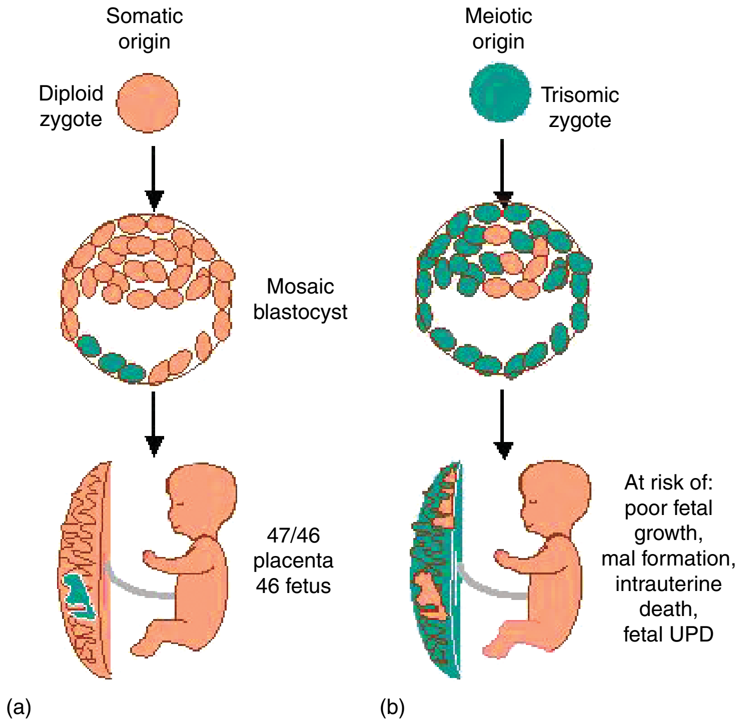

Figure 1 Origin of trisomy mosaicism may be somatic (a) or meiotic (b)

On the flip side, however, is the concern that there may be long-term consequences of mosaicism not apparent at birth. A number of malignancies are associated with chromosomally abnormal cells (*see* Article 14, **Acquired chromosome abnormalities: the cytogenetics of cancer**, Volume 1). Some examples include hepatoblastoma with trisomy 20, various hematological malignancies with trisomy 8 (Maserati *et al*., 2002), certain leukemias with trisomy 21, and gonadoblastoma with 45,X/46,XY mosaicism. While some of these trisomies arise by somatic missegregation in the affected tissue, some may be associated with undiagnosed low-level mosaicism already present at birth. For example, a case of erythroleukemia was diagnosed in a 16-month-old girl with normal development, in which the trisomy 21 cell line found in blood exhibited two different maternal alleles and was thus determined to be of meiotic origin (Minelli *et al*., 2001). Trisomy 8 in cases of myelodysplasia and acute leukemia can be found in other tissues in 15–20% of cases, suggesting an early embryonic origin (Maserati *et al*., 2002).

Malignancies are not the only impact of mosaicism. Skin pigmentation anomalies, such as hypomelanosis of Ito, and asymmetric growth are the clinical features that immediately raise the question of possible chromosomal mosaicism. Rheumatoid arthritis, osteoarthritis, and other inflammatory joint diseases have been associated with trisomy 7 mosaicism in the affected joints (Kinne *et al*., 2001), and trisomy 21 has been found at increased frequency in the peripheral lymphocytes of individuals with Alzheimer disease (Geller and Potter, 1999). The increase of

chromosomally abnormal cells with age may also contribute to the "decay" of the body in ways we do not yet understand.

Although, distinct from mosaicism, chromosomally distinct cells may also be found in an individual because of chimerism or microchimerism. In this case, the cells arise not from a single conceptus but from two separate individuals. True chimeras may result from the fusion of two distinct embryos early in development, but proven examples of this are very few. Some cases of 46,XX/46,XY mosaicism have probably been falsely assumed to be chimeras, when in fact they may result from two chromosome loss events from a 47,XXY conceptus (Niu *et al*., 2002). Microchimerism can occur in twin pregnancies, whereby cells from one twin can populate the haematopoietic stem cells of another twin through "twin to twin transfusion." Furthermore, there appears to be a normal exchange of cells between fetus and mother and vice versa during pregnancy that can persist throughout the life span of the recipient individual (Bianchi, 2000). The pregnancy need not go to term, and as many as 500 000 fetal nucleated cells are transfused following elective first-trimester termination of pregnancy. Some investigators have hypothesized that the presence of foreign white blood cells might help to explain certain autoimmune diseases that tend to be more common in women after the age of 40 (Bianchi, 2000; Nelson, 2003). There is also evidence for the involvement of maternal cells in the etiology of neonatal or juvenile autoimmune disorders (Stevens *et al*., 2003).

Clearly, chromosomal mosaicism and microchimerism play important roles in human disease, which are likely to be appreciated more as clinicians and researchers become more aware of their possible impact. However, tracking these rare cells throughout the body can be a real challenge for researchers. The first step in considering the role of low levels of abnormal cells is to rationally consider both the possibility that they may play a role in disease and also that they may not. Unbiased ascertainment of mosaic cases and long-term follow-up will be key to accurately evaluate these possibilities.

Short Specialist Review

Uniparental disomy

Aaron P. Theisen
Health Research and Education Center, Washington State University, Spokane, WA, USA

Lisa G. Shaffer
Sacred Heart Medical Center, Washington State University, Spokane, WA, USA

In the mid-nineteenth century, Gregor Mendel discovered that when round garden peas were crossbred with wrinkled garden peas, all of the offspring were round, regardless of the parental origin of each trait in the cross. The resultant principle of equivalence – that genes are expressed equally, no matter what the parental origin is – and its corollary, the biparental inheritance of autosomal genes, have become a central dogma of genetics. However, in recent decades, researchers have discovered several phenomena that challenge the conventional Mendelian notions of equal, biparental inheritance. Genomic imprinting, the unequal expression of alleles depending on the parent of origin, is perhaps the most clinically significant exception to Mendel's laws of inheritance. The clinical consequences of genomic imprinting may be unmasked when a pair of homologous chromosomes are abnormally inherited from a single parent. This situation is termed *uniparental disomy* (*UPD*).

Eric Engel first suggested UPD as a mechanism for human genetic disease in 1980 on the basis of observations made by Searle and others (Searle *et al*., 1971; Lyon *et al*., 1975) that mice with translocations were susceptible to nondisjunction (*see* Article 16, **Nondisjunction**, Volume 1), in which the homologous chromosomes comprising the translocation would malsegregate during gametogenesis (*see* Article 13, **Meiosis and meiotic errors**, Volume 1). Engel hypothesized that by mating these translocation carriers, a subset of offspring would receive a nullisomic gamete from one parent and a disomic gamete from the other parent, resulting in a chromosomally balanced individual with both chromosome homologs coming from one parent (Engel, 1980). Further research in the mouse by Cattanach and others (1985) provided the first evidence of the clinical effects of mammalian uniparental disomy; however, the existence of UPD in humans did not come until several years later, when the development of DNA-based polymorphic markers allowed the parental origin of chromosome homologs to be determined (Spence *et al*., 1988).

The first documented case of human UPD arose from the investigation of a child with cystic fibrosis and short stature (Spence *et al*., 1988). Marker analysis revealed

that the child inherited both chromosomes 7 from her mother. The cystic fibrosis was likely the result of the presence of a recessive disease allele on both copies of identical homologs of chromosome 7 inherited by the child. Spence *et al*. (1988) proposed three mechanisms in addition to the gametic complementation theory hypothesized by Engel (1980), including postfertilization error and the "rescue" of a conception either by the loss of an extra chromosome in a trisomy or the duplication of a single chromosome in a monosomy. The UPD can contain one copy of each of the contributing parent's homologs (heterodisomy) or two copies of one of the parent's chromosomes (isodisomy). Recessive disease alleles, such as that for cystic fibrosis, are exposed through isodisomies, which often result from a monosomy rescue or postfertilization recombination (Spence *et al*., 1988). UPD for nearly every chromosome has been documented as a result of the investigation of the abnormal inheritance of recessive disorders, including spinal muscular atrophy type III, osteogenesis imperfecta, and Bloom syndrome (reviewed in Cassidy, 1995; Shaffer, 2003).

Because of the high lethality of monosomic embryos and the requirement of a duplication event early in development, cases of UPD arising from a monosomy rescue are far rarer than those UPDs that arise after resolution of a trisomy. Mosaicism (*see* Article 18, **Mosaicism**, Volume 1) may result because of the presence of a mixture of trisomic cells and cells that have lost the extra chromosome copy. The trisomic cells in some conceptuses may be restricted only to the placenta, whereas the fetal cells contain normal chromosomal complements (termed *confined placental mosaicism*). Several UPD cases have been reported following a discrepancy between karyotyping performed on chorionic villus samples (CVS) from the placenta and amniotic fluid samples in which cells are derived from the fetus (Kalousek *et al*., 1993; Jones *et al*., 1995; Ledbetter and Engel, 1995).

Several structural chromosome abnormalities may prompt molecular investigations that may lead to the identification of UPDs, including Robertsonian translocations, nonacrocentric isochromosomes, marker chromosomes, derivative chromosomes, and reciprocal translocations (Shaffer *et al*., 2001a). Of these, Robertsonian translocations are the most likely to be involved in cases of UPD, probably due to their relatively high incidence in the human population and the increased risk of malsegregation during gametogenesis, which would result in aneuploid gametes (Berend *et al*., 2000). Resolution of trisomies may result in UPD. Malsegregation of structural abnormalities may result in gametic complementation and UPD; however, because gametic complementation requires two independent nondisjunction events, one in each parent, UPDs resulting from this mechanism are relatively rare.

Of the four mechanisms that may result in UPD, all but postfertilization error (somatic recombination) result in whole-chromosome uniparental disomies. Mitotic crossing-over may result in partial UPDs; sporadic cases of Beckwith–Wiedemann syndrome (BWS) (*see* Article 30, **Beckwith–Wiedemann syndrome**, Volume 1) are often caused by a partial paternal disomy of the distal short arm of chromosome 11 (Henry *et al*., 1991; Bischoff *et al*., 1995).

Studies of UPD in mouse and human have highlighted the differential maternal and paternal genetic contribution to development. Androgenotes, mouse embryos that contain only paternally derived chromosomes, exhibit poor growth while the extra-embryonic tissues develop relatively normally; in contrast, the

embryonic tissues of gynogenotes, which contain two copies of the maternal chromosomes, develop well, but the extra-embryonic structures fail to develop, resulting in embryonic death shortly after implantation (Surani *et al*., 1984; *see also* Article 28, **Imprinting and epigenetics in mouse models and embryogenesis: understanding the requirement for both parental genomes**, Volume 1). This phenomenon is the result of genomic imprinting and the developmental genetic need for contributions from both parents.

In humans, abnormal pregnancies in which the placenta appears as a cyst known as a hydatidiform mole demonstrate the same abnormal development: the moles, which contain all paternal chromosomes, consist entirely of placental tissue. The maternal counterpart, teratomas, which contain two copies of the maternal genome, contain only embryonic tissues (Jacobs *et al*., 1982). These examples suggest that, rather than the maternal and paternal genomes being equivalent, certain regions of the genome are not expressed equally from the maternal and paternal contributions. Because the differential contributions are not marked by changes to the DNA sequence, epigenetic modifications (chemical changes to the DNA or the surrounding proteins) must result in differential gene expression, depending on whether the genes are inherited from the mother or father.

UPDs may unmask additional phenotypic effects beyond those attributed to recessive disease through the duplication and subsequent overexpression, or deletion and lack of expression, of imprinted genes (*see* Article 26, **Imprinting and epigenetic inheritance in human disease**, Volume 1). For example, 25–30% of patients with Prader–Willi syndrome (PWS) (*see* Article 29, **Imprinting in Prader–Willi and Angelman syndromes**, Volume 1) have maternal UPD for maternal chromosome 15. The other 70% have deletions of a small part of paternal chromosome 15, indicating that the loss of a paternally expressed gene results in the syndrome. Conversely, maternal deletion of 15q in ~70% of cases or paternal disomy for chromosome 15 in ~5% of cases results in a clinically distinct disorder, Angelman syndrome (AS; Nicholls *et al*., 1989). The disparity between frequencies of UPD in the two syndromes is likely a result of higher rates of female nondisjunction than male nondisjunction (Abruzzo and Hassold, 1995). However, most cases of AS caused by UPD are isodisomy, likely due to a rescue of a monosomic conceptus, whereas maternally derived UPD cases in PWS are usually heterodisomic, due to a rescue of a trisomic conceptus. Because monosomies are less viable than trisomies and tend to result in miscarriage sooner, there is a smaller "window of opportunity" in which the monosomic conceptus can be rescued, likely resulting in fewer cases of isodisomy (Shaffer, 2003). In addition to maternal and paternal disomies 15, several other chromosomes show clinically distinct phenotypes due to imprinting, including paternal disomy 6, maternal disomy 7, partial paternal disomy 11, and maternal and paternal disomies 14 (Ledbetter and Engel, 1995; Shaffer *et al*., 2001b; Kotzot, 1999). Phenotypes suggestive of imprinting effects are also found in maternal disomy 2, maternal disomy 6, paternal disomy 9, maternal disomy 16, paternal disomy 16, and maternal disomy 20; however, either because of insufficient cases reported, conflicting reports in the literature, or the confounding effects of mosaicism, the imprinting effects for these chromosomes remain uncertain (Shaffer *et al*., 2001b; Shaffer, 2003).

Imprinting disorders often involve cognitive and growth problems. Patients with PWS, for example, have short stature and are frequently obese (Cassidy, 1984). In contrast, the major clinical features of BWS include overgrowth (Henry *et al.*, 1991). The differential growth effects of some imprinted syndromes – particularly PWS, AS, BWS, and Silver–Russell syndrome (SRS; maternal UPD7 and small stature) – may indicate a conflict between the paternal and maternal genomes over the amount of resources demanded of the mother by her offspring; paternally expressed genes would encourage embryonic growth at the expense of the mother, whereas maternally expressed genes would encourage decreased offspring size (Moore and Haig, 1991). However, contradictory evidence exists for a number of chromosomes, although this may simply indicate that the differential maternal and paternal contributions to development are more complex than what the original models predict (Hurst and McVean, 1997).

Although it is a relatively newly described phenomenon, genomic imprinting has been shown to play a key role in several developmental processes. Disruption of these normal dosage imbalances (Shaffer *et al.*, 2001b) by uniparental disomy has permitted key insights into the possible mechanisms and functions of these epigenetic modifications, the ramifications of which continue to challenge the seemingly unshakable concepts that Mendel observed in peas over 100 years ago.

Short Specialist Review

Cytogenetics of infertility

Maria Oliver-Bonet and Renée H. Martin
University of Calgary, Calgary, AB, Canada
Alberta Children's Hospital, Calgary, AB, Canada

1. Introduction

Infertility is a major problem in human society. Up to 15% of couples at reproductive age have either problems in conceiving or repetitive reproductive failures. Human fertility can be altered by many different factors, some of which are related to defined genetic syndromes or chromosome abnormalities, both in males and females (*see* Article 11, **Human cytogenetics and human chromosome abnormalities**, Volume 1). Chromosomal disorders occur more frequently among the infertile population. Studies in infertile males have shown that the incidence of constitutional chromosomal abnormalities is higher in these patients than in the fertile population. Depending on the definition of infertility, the average ranges between 2% in males with combined indications of infertility and 14% in azoospermic men, whereas the incidence of chromosome abnormalities in newborns is 0.7% (Shi and Martin, 2001). Aberrant karyotypes have also been detected in 4.8% of women who are partners of infertile men scheduled for intracytoplasmic sperm injections (ICSI) (Gekas *et al*., 2001). The presence of a karyotypic abnormality can reduce fertility in two different ways. First, interruption of gametogenesis can lead to a decrease in the number of germ cells expected. Second, the production, through the meiotic process, of genetically unbalanced gametes leads to either embryonic or fetal death or to the birth of children with mental and physical disabilities.

2. Chromosomal aneuploidies

Somatic chromosome aneuploidies (loss or gain of a chromosome) are not only the most frequent type of anomaly but also those with the main clinical consequences (*see* Article 16, **Nondisjunction**, Volume 1). Klinefelter syndrome (XXY males) is the most common anomaly found among infertile males attending reproductive clinics. Apparent nonmosaic 47,XXY males are usually azoospermic, while mosaic 47,XXY/46,XY individuals are able to produce different amounts of spermatozoa that range from severe oligozoospermia to normozoospermiaxy (*see* Article 18, **Mosaicism**, Volume 1). Fluorescence in situ hybridization (FISH) analysis of the spermatozoa of these patients has demonstrated that the frequencies of sperm

chromosome aneuploidies in nonmosaic and mosaic Klinefelter patients range from 2 to 25% and from 1.5 to 7.0%, respectively, which is significantly higher than in controls (Shi and Martin, 2001). Specifically, the mean frequencies of XY and XX spermatozoa in nonmosaic and in mosaic patients are 8.1 and 3.6%, and 1.8 and 0.8%, respectively (Egozcue *et al*., 2000; Shi and Martin, 2001).

Nowadays, there is a debate in the literature on the meiotic behavior of chromosomes in Klinefelter syndrome patients. Some authors support the idea that small numbers of XXY spermatogonial stem cells are able to undergo meiosis (Yamamoto *et al*., 2002) and that these few cells are responsible for the higher XY and XX disomy frequency found in the sperm of these patients. Alternatively, other authors suggest that XXY cells are unable to enter meiosis and that the XY line is actually the only one able to produce viable spermatozoa (Blanco *et al*., 2001). According to these authors, the unusual frequency of sex disomy found in the sperm of these patients may be due to an abnormal testicular environment, which may itself predispose the sex chromosomes to nondisjunction events (Mroz *et al*., 1999).

Male carriers of an extra Y chromosome (47,XYY) exhibit a variable degree of fertility. Three color-FISH analyses on sperm of 47,XYY men have shown that XY and YY disomy represent only 1% or less of the sperm population (Shi and Martin, 2000). These results, together with meiotic analysis performed on testicular samples of 47,XYY patients, support the hypothesis that the extra Y chromosome is lost from most germ cells even before meiosis begins. However, some authors have reported the presence of an X univalent plus a YY bivalent at pachytene stage, thus suggesting that XYY cells are able to undergo and even survive meiotic processes (Solari and Rey Valzacchi, 1997). The frequency of autosomal aneuploidies has also been investigated in 47,XYY males, in order to assess the possibility of interchromosomal effects (ICE), but no convincing evidence for such effects has been found in these men (Shi and Martin, 2000).

Women with 47,XXX karyotype are able to conceive, without a high risk for aneuploid offspring. Apparently, the extra X chromosome is lost in premeiotic stages. Thus, these women produce only oocytes with a single X. However, a recent study suggests that the triple X syndrome may be associated with premature ovarian failure and also with poor pregnancy outcome (Goswami *et al*., 2003). On the other hand, women affected by Turner's syndrome (45,X) are infertile, because their oocytes are lost during early gestation stages. A recent study reported that approximately 70% of germ cells were apoptotic in the ovary of a 20-week old 45,X fetus (Modi *et al*., 2003). Some oocytes may be capable of survival and maturation; indeed, some follicles have been found in adolescent Turner's patients and spontaneous pregnancies are seen in 2–5% of these women (Hreinsson *et al*., 2002). To date, it is still unclear whether these oocytes are chromosomally balanced.

3. Structural chromosomal anomalies

Somatic structural chromosome anomalies include translocations (both reciprocal and Robertsonian), pericentric and paracentric inversions and insertions (*see* Article 11, **Human cytogenetics and human chromosome abnormalities**,

Volume 1). The percentage of unbalanced gametes found in male and female Robertsonian translocation carriers ranges from 3 to 27% and from 7 to 68% respectively (Guttenbach *et al*., 1997). Reciprocal translocation carriers display an unbalanced average fraction of 53% for males (Shi and Martin, 2001) and 70% for females (Durban *et al*., 2001). In addition, evidence from studies of preimplantation genetic diagnosis suggest that ICE seem to play a role only in the case of Robertsonian translocations (Gianaroli *et al*., 2002; *see also* Article 21, **Preimplantation genetic diagnosis for chromosome abnormalities**, Volume 1). Inversions, either paracentric or pericentric, have a risk of generating unbalanced gametes owing to meiotic recombination processes within the inverted segment. Generally, long inversion segments have a larger risk than short segments. Insertions usually have a high risk of abnormal offspring, the average risk being 32% for the male carrier and 36% for the female (Van Hemel and Eussen, 2000). The incidence of this risk is closely related to the size of the inserted segment – small segments usually have greater risk than large segments.

4. Infertile individuals with a normal somatic karyotype

Reproductive difficulties have also been associated with cytogenetic abnormalities in the germ cells of infertile individuals with a normal constitutional karyotype both in males (Egozcue *et al*., 2000) and females (Plachot, 2001). These abnormalities include meiotic pairing defects and a low incidence of recombination sites. The occurrence of such anomalies can affect the normal course of meiosis through a total or partial meiotic arrest (*see* Article 13, **Meiosis and meiotic errors**, Volume 1). The control upon these aberrant cells is especially noticeable at pachytene, indicating the existence of a universal pachytene checkpoint. Data obtained in different studies strongly suggest that this control mechanism is more permissive in females than in males, which means that whereas spermatogenesis tends to halt when an anomaly is encountered, oogenesis continues, with the consequence of an increased frequency of aneuploidy in the resultant gametes. Indeed, an association between the fertility status of women and the incidence of anomalies in the oocytes was found after analyzing human oocytes that remained unfertilized after in vitro fertilization (IVF) protocols: 13.3% of them were hypohaploid, 8.1% were hyperhaploid, 3.5% were diploid, and 1.6% carried structural abnormalities (Plachot, 2001). On the other hand, the presence of apoptotic processes in males does not preclude a variable number of germ cells from becoming viable aneuploid spermatozoa. Thus, despite having a normal somatic karyotype, sperm collected from infertile men exhibit a significantly increased frequency of chromosomal abnormalities that can also result in both fertility reduction and aneuploid progeny. Different sperm FISH analyses have reported a higher incidence of disomy in infertile patients. Particularly, the frequency of sex chromosome aneuploidy is markedly increased, up to 2–3 times the aneuploidy rate observed in control donors (Shi and Martin, 2001). This frequency is in agreement with the frequency of 1% sex chromosomal abnormalities reported from prenatal diagnoses after ICSI (Liebaers *et al*., 1995).

5. Techniques used in cytogenetic analysis of infertility

The main source of human oocytes for analysis is oocytes that failed to fertilize after IVF. In addition to the egg cells, the first polar body (PB1), which carries a haploid set of chromosomes complementary to the set carried by the oocyte, is also useful in order to obtain information about the incidence of chromosomal anomalies derived from the first meiotic division. After spreading and fixation, chromosome contents can be analyzed by different cytogenetic approaches (Pujol *et al*., 2003).

The content of the spermatozoa can be analyzed using two different methods. The human-hamster system allows analysis of the whole chromosome complement of individual sperm cells (Martin *et al*., 1984). However, the number of chromosome complements that can be analyzed for each patient is, from the statistical point of view, rather low. A quantitative improvement in sperm analysis was the application of FISH techniques on chemically decondensed sperm nuclei (Wyrobek *et al*., 1994). This is a quick and comparatively simple method, which allows the analysis of thousands of spermatozoa in a relatively short time. This method also has its own limitations, though. It is based on an indirect method of detection of certain chromosomes, and thus more prone to error than direct karyotyping of human sperm.

Human meiotic processes have been analyzed using the microspreading technique (Evans *et al*., 1964). This measures the number and position of crossover events within each bivalent at diakinesis-metaphase I stage, and permits the study of all meiotic stages. Nowadays, the application of FISH to meiotic chromosomes enables the analysis of the meiotic behavior of specific chromosomes. However, the special morphology and highly contracted state of the bivalents during the diakinesis-metaphase I stage make the exact estimation of physical distances among the chiasmata of a bivalent troublesome. Immunocytogenetic approaches have also been used to analyze meiotic processes in humans (Barlow and Hultén, 1996). Studies using this method combined with FISH and multi-FISH techniques have provided information about the pairing process of homologous chromosomes during meiosis I. Moreover, the application of both analyses in parallel allows not only the identification of specific pairs of bivalents but also the study of meiotic exchange rates of the target chromosomes (Oliver-Bonet *et al*., 2003).

Cytogenetic research has proved to be one of the most successful tools in the study of fertility. By different approaches, cytogenetic analysis has provided us with significant information about many of the processes that take place during human gametogenesis. We must expect that with the introduction of new and increasingly powerful techniques, especially those resulting from the fusion of conventional cytogenetic techniques and molecular genetic approaches, we will be soon able to obtain a deeper knowledge about both the factors affecting and the basic mechanisms regulating human fertility.

Short Specialist Review

Preimplantation genetic diagnosis for chromosome abnormalities

Santiago Munné
Yale University, New Haven, CT, USA

1. Introduction

Preimplantation genetic diagnosis (PGD) is the earliest form of prenatal diagnosis, and usually involves the analysis of a single cell after biopsy from a three-day old embryo created through assisted reproductive techniques (ART), or sometimes the first and second polar bodies of the eggs prior fertilization, also through ART. Because the embryo should be replaced in the future mother in no more than one or two days after biopsy and as there are only one or two cells for analysis, the diagnostic tests must be fast and highly sensitive. However, obtaining analyzable metaphases of karyotyping quality from a single cell is not possible even with cell-conversion methods (Willadsen *et al*., 1999; Verlinsky and Evsikov, 1999); so the analysis for cytogenetic purposes is performed using FISH, which allows chromosome enumeration of interphase cell nuclei, that is, without the need for culturing cells or preparing metaphase spreads. Since 1993, FISH has been used for PGD of common human aneuploidies with either blastomeres (cells from 2- to 16-cell stage embryos) or oocyte polar bodies (Munné *et al*., 1993; Munné *et al*., 1995a,b; Munné *et al*., 1998b; Munné *et al*., 1999; Munné *et al*., 2003; Verlinsky *et al*., 1995; Verlinsky *et al*., 1996; Verlinsky *et al*., 1998; Verlinsky *et al*., 2001; Verlinsky and Kuliev, 1996; Gianaroli *et al*., 1997; Gianaroli *et al*., 1999; Gianaroli *et al*., 2001b; Pehlivan *et al*., 2002; Kahraman *et al*., 2000; Rubio *et al*., 2003). Currently, probes for at least chromosomes X, Y, 13, 15, 16, 18, 21, and 22 are being used simultaneously (Munné *et al*., 2003), with the potential of detecting 83% of aneuploidies found in spontaneous abortions (Jobanputra *et al*., 2002).

2. PGD to improve pregnancy outcome in ART

PGD was first thought of as a tool for selecting against genetically abnormal embryos from couples carrying genetic diseases; but about 90% of the PGD cycles performed so far have been for aneuploidy to improve the pregnancy outcome of ART patients, with over 5000 cases performed to date for that purpose (Munné *et al*., 1999; Munné *et al*., 2003; Gianaroli *et al*., 1999; Gianaroli *et al*., 2001b;

ESHRE PGD Consortium Steering Committee, 2002; Verlinsky and Kuliev, 2003) and close to a thousand babies born thereafter (Verlinsky *et al*., 2004).

The rationale for using PGD to increase pregnancy rates and reduce miscarriage rates is as follows. Oocyte quality is the major cause of reduced implantation with advancing maternal age (Navot *et al*., 1994), and one of the clearest links so far between maternal age and embryo competence is aneuploidy. The increase in aneuploidy with maternal age in spontaneous abortuses and live offspring (Hassold *et al*., 1980; Warburton *et al*., 1980; Warburton *et al*., 1986; Simpson, 1990) has also been observed in embryos and oocytes (Munné *et al*., 1995a; Márquez *et al*., 2000; Dailey *et al*., 1996) but with much higher rates of chromosome abnormalities than in spontaneous abortions, which indicates that a sizable part of chromosomally abnormal embryos are eliminated before clinical recognition. This embryo loss, rather than endometrial factors, largely accounts for the decline in implantation with maternal age.

To compensate for the low implantation potential of human embryos created in vitro, fertility centers normally generate a larger cohort of embryos (average >10); those with the highest potential to implant are then selected on the basis of morphology and developmental characteristics. Unfortunately, trisomy is not correlated with embryo morphology or development (Munné *et al*., 1995a; Márquez *et al*., 2000), and only some monosomies can be selected against by culturing the embryos to blastocyst stage (Sandalinas *et al*., 2001).

Because of the correlation between aneuploidy and declining implantation with maternal age, we hypothesized that negative selection of chromosomally abnormal embryos could reverse this trend (Munné *et al*., 1993). While the probes currently used in PGD check only a limited number of chromosomes, the results so far indicate that PGD of aneuploidy actually does increase implantation while reducing trisomic offspring and spontaneous abortions (Munné *et al*., 1999; Munné *et al*., 2003; Gianaroli *et al*., 1999; Gianaroli *et al*., 2001a,b; Werlin *et al*., 2003).

As determined in a recent study, the chromosomes most involved in aneuploidy at the cleavage stage (first 3 days of embryo development) are different than those found in prenatal diagnosis (Munné *et al*., 2004). So when the most common chromosomes are analyzed by PGD with eight or more probes, including probes for chromosomes 13, 15, 16, 18, 21, and 22, the implantation rate (embryos implanting/embryos replaced) doubles.

In one study, we observed a significant twofold increase of implantation, from 10.2 to 22.5% ($p < 0.001$) (Gianaroli *et al*., 1999); in another more recent study with an older population (average age 40), and with two or less previously failed IVF attempts, we found a 20% implantation rate after PGD compared to 10% in the control group ($p = 0.002$) (Munné *et al*., 2003).

It is clear that not only does implantation reduce with advancing maternal age but also those embryos that do implant have a higher risk of chromosomal abnormality and miscarriage. Since the objective of ART is to ensure a healthy baby for couples seeking to conceive, both factors are extremely important.

FISH with probes for 13, 15, 16, 18, 21, 22, X, and Y can detect 83% of all chromosomally abnormal fetuses detected by karyotyping (Jobanputra *et al*., 2002). Since this combination of probes is the current standard (Munné *et al*., 1999; Gianaroli *et al*., 1999), PGD is able to eliminate close to 80% of all chromosomally

abnormal embryos at risk of causing a miscarriage. Among many examples, two studies reported abortion rates of only 9% after PGD in women >36 years (Munné *et al*., 1999; Gianaroli *et al*., 2001a,b) compared to the 24% spontaneous abortion expected for such populations of infertile patients (SART-ASRM, 2000).

Increased implantation and decreased spontaneous abortion result in a higher chance of patients achieving viable pregnancies (Munné *et al*., 1999). However, PGD works properly only when a larger group embryos is available for testing in a given procedure. If patients have less than five embryos available, then replacing all the embryos will in general give the same result as if PGD had been performed.

3. PGD to reduce the risk of aneuploid conceptions

The current PGD technique works by analysis of a single cell with an error rate around 10%. This error rate is mostly due to mosaicism, which is very common in human cleavage-stage embryos (see review Munné *et al*., 2002). Thus, when diagnosing trisomic offspring, PGD can significantly reduce the occurrence but not completely prevent it. Indeed, four misdiagnoses have already occurred after PGD (Munné *et al*., 1998b; Gianaroli *et al*., 2001a). Nevertheless, the rate of trisomic offspring detected after PGD is significantly lower than expected ($p < 0.001$). For instance, 2 of 666 (0.3%) fetuses were found with aneuploidies for chromosomes XY, 13, 15, 16, 18, 21, and 22 (Munné *et al*., 2003 and unpublished results) compared to a 2.6% rate expected in a population of the same age range (Eiben *et al*., 1994). Interestingly, the reduction from 2.6% to 0.3% is a 90% reduction, which is as expected if the error rate is indeed 10%. Similarly, Verlinsky *et al*. (2001) reported 140 healthy children born after PGD of aneuploidy using polar body analysis, with no misdiagnoses.

4. PGD for translocations

Balanced translocations occur in 0.2% of the neonatal population. However, they are identified in 0.6% of infertile couples, 2–3.2% of infertile males requiring intracytoplasmic sperm injection, and 9.2% of fertile couples experiencing three or more consecutive first-trimester abortions (Testart *et al*., 1996; Meschede *et al*., 1998; Van der Ven *et al*., 1998; Stern *et al*., 1996; Stern *et al*., 1999). PGD for translocations can reduce spontaneous abortion and minimize the risk of conceiving an unbalanced baby, thus being a realistic alternative to prenatal diagnosis and pregnancy termination of unbalanced fetuses. So far there have been close to 500 cycles of PGD of translocations performed worldwide (Munné *et al*., 2002; Verlinsky *et al*., 2002; Cieslak *et al*., 2003; Gianaroli *et al*., 2003).

4.1. Methods

Several approaches to PGD of translocations have been developed. The first involved the analysis of first polar bodies, after the observation that more than 90%

of first polar bodies fixed for 6 or fewer hours after retrieval are in metaphase stages (Munné *et al*., 1998a). The translocation can then be identified using chromosome-painting probes for the two chromosomes involved in the translocation (Munné *et al*., 1998c,d; Durban *et al*., 2001).

Cell-conversion methods have also been used to transform blastomere nuclei (usually in interphase to metaphase) by fusing them to oocytes or zygotes (Willadsen *et al*., 1999; Verlinsky and Evsikov, 1999; Evsikov *et al*., 2000; Verlinsky *et al*., 2002), achieving close to 80% rates of analyzable metaphases. Alternatively, Tanaka *et al*. (2004) observed 4–6-cell stage embryos every hour, and when the nuclear envelope of a blastomere disappeared, the blastomere was biopsied within an hour. Disappearance of nuclear envelope was observed in 89% of embryos, and all produced analyzable metaphases.

Two different interphase approaches have also been developed for PGD of translocations. The first developed specific probes spanning the breakpoints of each translocation (Munné *et al*., 1998c; Weier *et al*., 1999) or inversion (Cassel *et al*., 1997). The second used probes distal to the breakpoints or telomeric probes in combination with proximal or centromeric probes, either for translocations (Munné *et al*., 1998c; Munné *et al*., 2000; Pierce *et al*., 1998; Van Assche *et al*., 1999) or inversions (Iwarsson *et al*., 1998). The exception is a Robertsonian translocation (RT), for which chromosome enumerator probes are used to detect aneuploid embryos (Conn *et al*., 1998; Munné *et al*., 1998c; Munné *et al*., 2000). Only the first approach (spanning probes) can differentiate between balanced and normal embryos.

4.2. *Results*

For most translocation patients, the risk of consecutive pregnancy loss is their major incentive in enrolling in a PGD program. The unbalanced products of a translocation are usually lethal and therefore the true risk is that of pregnancy loss. We have demonstrated that PGD of translocations substantially increases a couple's chances of sustaining a pregnancy to full term (Munné *et al*., 1998e; Munné *et al*., 2000). So far, 115 patients undergoing PGD for translocations have lost 84% (233/278) of their prior conceptions, but after PGD only 5% (4/78) was lost (Munné *et al*., 1998e; Munné *et al*., 2000, and unpublished data). Data from Verlinsky's group also indicates a significant reduction in spontaneous abortions to 20% (7/34) (Verlinsky *et al*., 2002; Cieslak *et al*., 2003), when 88% of pregnancies in these patients prior to undertaking PGD procedure resulted in spontaneous abortions.

However, some translocation patients produce 80% or more unbalanced gametes, and with the 50% baseline of chromosome abnormalities in cleavage-stage human embryos, it is nearly impossible to find normal ones for replacement. Previous studies have used clinically recognized pregnancies to formulate rules to predict unbalanced offspring (Jalbert *et al*., 1988). However, these specimens were probably the most viable segregation types because selective processes had already occurred. Thus, when analyzing zygotes and preimplantation embryos, it is not surprising that different translocations involving the same chromosomes show very different meiotic behavior (Escudero *et al*., 2000; Van Assche *et al*.,

1999). Escudero *et al*. (2003) determined the level of chromosome abnormalities in spermatozoa that would preclude a chromosomally normal conception, and found that the percentages of abnormal gametes and of abnormal embryos were correlated, thereby establishing that patients with 65% or fewer chromosomally abnormal spermatozoa have a good chance of conceiving.

5. Molecular methods for PGD of chromosome abnormalities

Ultimately, speedy and efficient analysis of all 24 chromosomes is PGD's true goal, as some embryos diagnosed as normal are undoubtedly still abnormal for other aneuploidies not analyzed in current protocols. One approach still needing improvement is comparative genome hybridization (CGH) (Kallioniemi *et al*., 1992). For CGH of single cells, the whole genome of the cell must be amplified (Wells *et al*., 1999). Trials applied to human blastomeres from discarded embryos have promising results (Wells and Delhanty, 2000; Voullaire *et al*., 1999; Voullaire *et al*., 2000), but so far, the process takes too long. To gain enough time for analysis, Wilton *et al*., (2001, 2003) applied this method to blastomeres from embryos that were frozen after biopsy, and the first babies have recently been borne following this procedure. However, cryopreservation and thaw destroys some embryos and ultimately outweighs the benefits of CGH.

Recently, we have been able to obviate cryopreservation by applying CGH to polar bodies and get results prior to embryo replacement on day four of development (Wells *et al*., 2002). But as with any polar body analysis, postzygotic abnormalities, which account for more than half of all abnormalities, as well as paternally derived aneuploidies, are not detectable.

DNA microarrays are being developed for aneuploidy and translocation analysis (Weier *et al*., 2001), but as presented in the last International symposium of PGD, current methods still need improvement to differentiate in single cells ratio changes of 0.5 in order to be used for PGD (Leight *et al*., 2003).

Once optimized, microarrays will have the advantage over CGH of being more robust and probably faster, and possibly not requiring embryo freezing. Also, they will supply redundancy and more accurate diagnosis of subchromosomal regions useful for translocation analysis.

Basic Techniques and Approaches

FISH

P. Nagesh Rao
David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

Mark J. Pettenati
Wake Forest University School of Medicine, Winston-Salem, NC, USA

Standard or conventional chromosomal banding analysis is limited to actively dividing cells and the resolution is limited to chromosomal aberrations greater than 3 Mb in size. On the other hand, fluorescence in situ hybridization (FISH) has developed into a meaningful and clinically accepted higher resolution method for analyzing the genetic characteristics of cells. Different FISH technologies provide increased resolution for the elucidation of structural chromosome abnormalities that cannot be resolved by more conventional cytogenetic analyses, including microdeletion syndromes, cryptic or subtle duplications and translocation, complex rearrangements involving many chromosomes, and marker chromosomes. There is a broad array of FISH techniques for both diagnostic and research applications. The FISH procedure has been developed for the tagging of DNA and RNA with labeled nucleic acid probes, and is a process whereby chromosomes or portions of chromosomes are vividly painted with fluorescent molecules that anneal to specific regions. This technique has been used widely for gene mapping and for the identification of chromosomal abnormalities. The method enables enumeration of multiple copies of chromosomes or detection of specific regions of DNA or RNA that represent associations with certain genetic characteristics and infectious diseases. Utilization of the FISH methods requires two essential components. The first is a nucleic acid probe that is complementary to the chromosome region of interest and the second is a buffer that solubilizes the probe and potentiates the denaturation of the cellular proteins and strands of DNA and RNA to be hybridized. The advent of fluorescent dyes for use as labels has made it possible to visualize multiple probes at the same time. This has opened up new possibilities for investigating and diagnosing diseases. There are now whole batteries of commercially available probes that can be used to identify each of the human chromosomes and can be used to identify cells in which chromosomal aberrations occur. Probe hybridization conditions generally depend on the probe's base-pair sequence and length of bases required to span the region of interest. Generally, probes less than 40 bases long are synthetically manufactured and probes that range from 80 Kb to 1 Mb long are manufactured with molecular biology methods using cosmids, YACs, PACs, or BACs. Probes can also be manufactured with PCR

techniques. The FISH probes that are developed in the labs have to be optimized for the FISH procedure. It is also important to compromise between maximizing the sensitivity of the test and minimizing the cost of the study. As hybridization efficiency increases proportionally with the increasing target size, the larger YAC and BAC probes usually give high-efficiency signals, and thus fewer cells need to be scored. In contrast, small single-copy signals hybridize less efficiently; thus, more cells need to be evaluated. The key criteria for development of probes for the FISH technique include bright signal intensity, compactness, and retention of cellular and nuclear morphology. These features provide a signal that is visible at lower magnification, thereby minimizing interference from cross hybridization to other genomic targets. The protocols developed for use with commercially available probes for labeling chromosomes in interphase nuclei and metaphase preparations, are also compatible with synthetically, biologically, or enzymatically lab-produced probes. The buffers used should also be compatible with either direct or indirect labeled fluorescent probes, optimize nucleic acid probe performance for rapid hybridizations to provide bright signals and low background, same-day hybridizations with results ranging from 30 min to overnight depending on probe characteristics.

For all interphase FISH analyses, it is important to establish diagnostic cutoff levels using the probe of choice and a series of normal controls for the type of cell under investigation. These must be established in the laboratory and cannot be adopted from other studies. The addition of different fluorescent labels and the selection of fluorescent dyes have also added variability to the technology method. Further, after labeling with FISH, it is often necessary to scan, detect, and enumerate the fluorescently labeled spots. In order to computerize the images for analysis, it is essential to have low background, specific and uniform labeling, and bright label intensities. After FISH, slides should be stored in the dark, either refrigerated or frozen, and are stable for at least 3 months.

Three different types of probes are commonly used, each with different ranges of applications.

Gene-specific probes target DNA sequences present in only one copy per chromosome. They are used to identify chromosomal translocations, inversions and deletions, contiguous gene syndromes, and chromosomal amplifications in interphase and metaphase chromosomes (Figure 1). Repetitive sequence probes bind to chromosomal regions that are represented by short repetitive base-pair sequences that are present in multiple copies (e.g., centromeric and telomeric probes). Centromeres are usually A-T rich, whereas telomeres are known to have repetitive TTAGGG sequences. Centromeric probes are extremely useful for identifying marker chromosomes and for detecting copy number chromosome abnormalities in interphase nuclei (Figure 2). On the other hand, telomeric probes are frequently used to identify subtle or submicroscopic chromosomal rearrangements. The relative ease of performance and high resolution (0.5 Mb) of repetitive sequence FISH has made it popular to screen for the common chromosomal aneuploidies, subtelomeric deletions, and marker chromosomes.

Whole-genome painting probes (WCP) are complex DNA probes that are generated by degenerate oligonucleotide polymerase chain reaction (DOP-PCR) or through flow sorting. WCP paints have high affinity for the whole chromosome

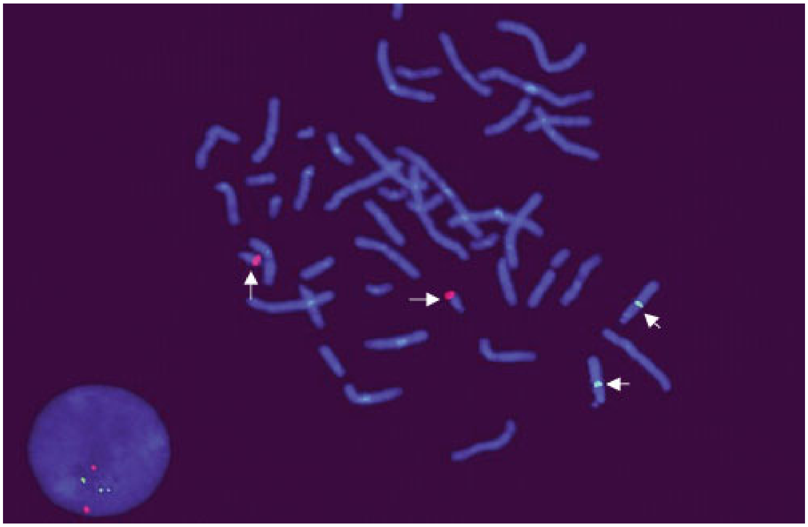

Figure 1 Locus-specific single-copy DNA probes mapping to the long arm of chromosome 21q22 (Red signals) and chromosome 13q14 (Green signals)

along its entire length, with the exception of the centromeric and telomeric regions (Figure 3). These probes are most suitable for identifying genomic imbalances in metaphase chromosomes, especially the complex chromosomal arrangements observed in many cancers. Two variants of the WCP have been developed, multicolor-FISH (M-FISH) and spectral karyotyping (SKY). WCP probes have been developed that paint all human chromosomes in different colors (48 paints). And WCP can also offer simultaneous detection of each arm of all human chromosomes in a single hybridization. This technique is usually used in conjunction with chromosomal banding techniques for a more precise identification of chromosome aberrations. The two greatest limitations of WCP are that there must be extensive knowledge of genetic abnormality to enable the correct selection of the probes – unless the full complement of paints is to be used – and there is limited resolution to detect chromosomal inversions and very small deletions/amplifications and translocations due to its limited resolution of greater than 2–3 Mb.

Comparative genomic hybridization (CGH) is a molecular cytogenetic technique that emerged from FISH and standard cytogenetics to look for genome-wide DNA copy number changes in patients with a possible chromosomal disorder. This technique is especially valuable because, unlike standard cytogenetics, cell culture is not necessary. CGH can be performed on DNA extracted from archival tissue as well as from fresh-frozen specimens. Chromosomal copy number changes can be detected without having to selectively perform FISH for a specific chromosomal sequence. Briefly, the CGH involves two-color FISH of tumor and reference DNA to normal metaphase chromosomes. In order to prevent nonspecific hybridization, the differentially labeled tumor and control DNA are mixed together with Cot-1 DNA (containing repetitive sequences of the genome). Images of metaphase spreads are obtained with a CCD camera and fluorochrome-specific optical filters to

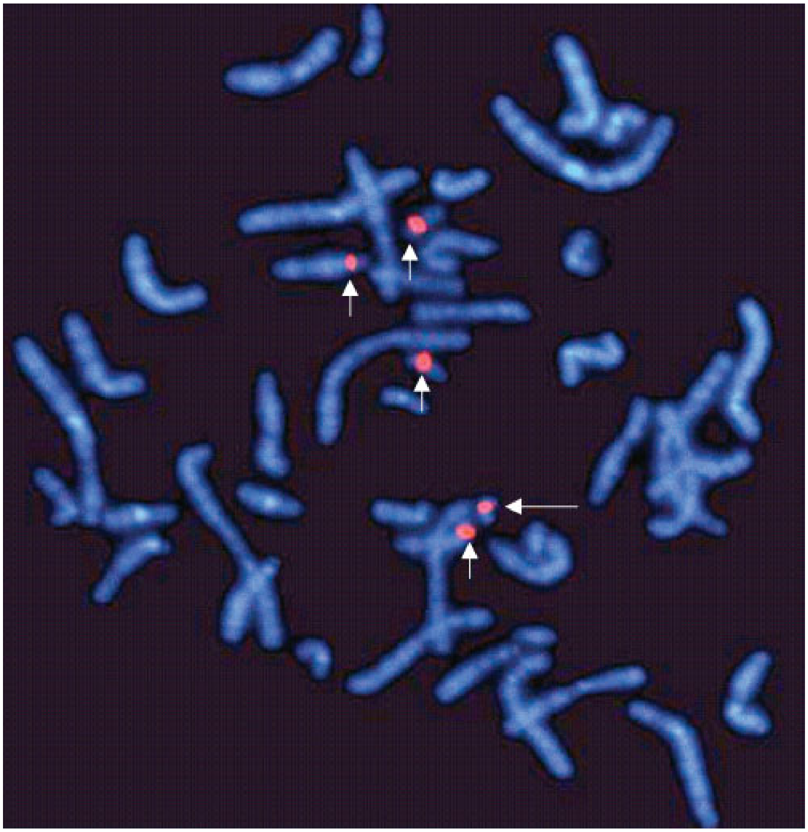

Figure 2 Repetitive sequence probes binding specifically to the centromeres of chromosome 14 and 22 (short arrows). The fifth signal (long arrow) shows a marker chromosome derived from either chromosome 14 or 22

capture the FITC (fluorescein-5-isothiocyanate) and TRITC (tetramethylrhodamine isothiocyanate) fluorescence. The copy number changes in the genome relative to the normal are assessed on the basis of differences in fluorescence intensities along the chromosome. The limitations of this technique include resolution of 3–10 Mb, manual hybridization reactions, and high cost. Recently, array-based formats of CGH (array CGH) have emerged into clinical practice as an alternative. In this procedure, the metaphase chromosomes are replaced with specific DNA sequences spotted in arrays on a glass slide. These DNA sequences may be either large insert genomic clones (e.g., BACs or oligonucleotides-synthesized short DNA sequences. The array readout is digital and quantitative. The greatest advantage of these techniques is the resolution.

The human BAC arrays for CGH consist of linker-adapter PCR representations of BAC clones spotted onto a variety of slide substrates. Hybridization to the human BAC arrays allows detection of single-copy gains and losses. The applications of BAC array technology include identification of diagnostic and prognostic chromosomal aberrations in birth defects, mental retardation, and cancers. The

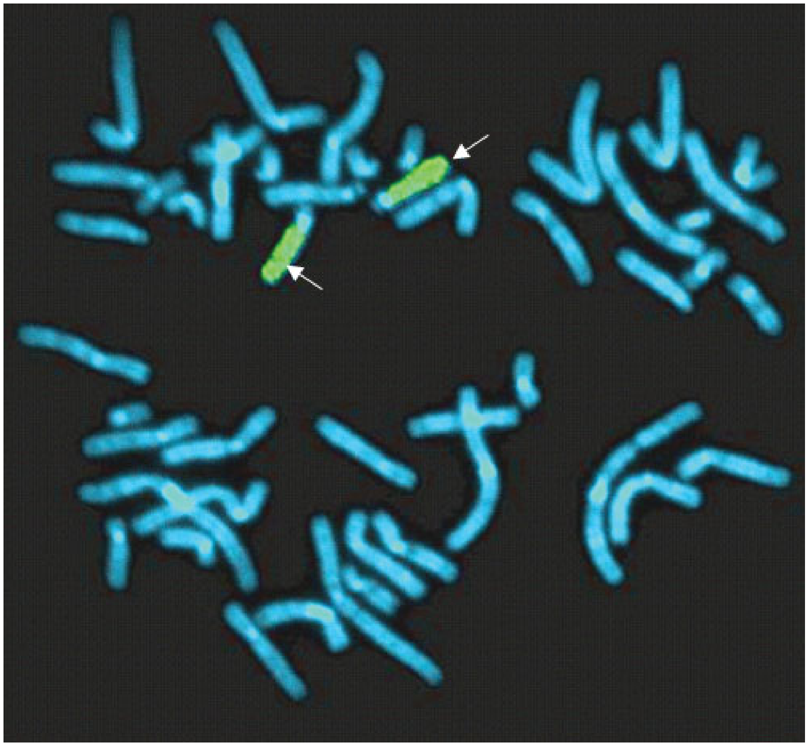

Figure 3 A metaphase cell showing two chromosome 15s with whole-chromosome paint probes (arrow, green signal) of chromosome 15

whole-genome analysis usually requires anywhere from several hundred nanograms to a couple of micrograms of genomic DNA, depending on the source of BAC arrays. One commercially available kit for human BAC arrays currently contains 2632 BAC clones distributed approximately uniformly at a spacing of approximately 1 Mb across the genome. Each clone contains at least one sequence tag that is mapped to the human genome sequence. The kit is composed of BACs that are spotted in duplicate allowing greater precision of the results. Clones containing unique sequences near the telomeres and clones containing genes known to be significant in cancer are included. Higher-density whole-genome- and chromosome-specific arrays have been developed in research laboratories with the goal of improving resolution. This slide format uses relatively large amounts of genomic DNA (approximately 6–10 ∝g at 400–500 ng uL^{-1}) from test specimens for analysis. The signal is highly quantitative and reproducible with low "background noise". However, the preparation and spotting of thousands of BACs onto slides is cumbersome and labor-intensive. The resolution is limited to the map distance between each clone. The signals produced by low copy, centromeric and telomeric repeats may be nonlinear, and thus nonindicative of the copy number. Array-based CGH technology offers 45 kb to 1 Mb resolution, depending on the density of the array.

Oligonucleotide-based arrays have gained popularity in the scientific community to monitor the quantitative expression of the arrayed genes in mRNA populations from cell/tissues, and more recently has been applied to detect DNA sequence and copy number polymorphisms in genomic DNA – array CGH. In brief, the arrays contain oligonucleotides matching all wild-type and single nucleotide substitution sequences in a gene, thus providing the basis for detecting single nucleotide polymorphisms (SNPs) as well as genomic copy number polymorphisms. Oligonucleotide array CGH can be applied to testing for mutations, as well as short- and long-range deletions and duplications in the genome, including aneuploidies and gene amplifications. When DNA derived from somatic (i.e., cancerous) cells and normal tissues is compared, loss of heterozygosity events can be detected. The resolution is limited by the density of the oligonucleotide arrays – currently 45–85 kb. Higher-density SNP arrays are currently undergoing β-testing in several commercial outfits, and these will greatly increase the ability to detect small regions of chromosomal changes and to identify the boundaries of the regions of loss or gain, thereby delineating candidate genes. Additional improvements will come from high-throughput automation of the process, including data analysis, and from development of protocols for handling fragmented DNA.

It is important to emphasize that the FISH methodologies reviewed here complement, but do not replace, standard chromosome banding analysis. Every technique has its strengths and limitations.

Comparative genomic hybridization

Brynn Levy
Mount Sinai School of Medicine, New York, NY, USA

1. Introduction

The history of human cytogenetics spans approximately 130 years from when chromosomes were first observed in plant material by Eduard Strasburger in 1875 and in animals by Walter Flemming in 1879–1889 (Lawce and Brown, 1997). However, the major advances in cytogenetics occurred in the 1950s when colchicine and hypotonic treatments were introduced (Hsu, 1952; Hughes, 1952; Makino and Nishimura, 1952) and 1970s with the development of various banding techniques that utilized either fluorescent dyes or Giemsa stain (Drets and Shaw, 1971; Patil *et al*., 1971; Seabright, 1971; Sumner *et al*., 1971) and enabled structural changes to be discerned and correlated with clinical phenotypes (Hirschhorn *et al*., 1973). The combination of molecular and cytogenetic techniques in the early 1970s led to the field of molecular cytogenetics, which now plays a significant role in both clinical diagnostics as well as clinical research. The in situ hybridization (ISH) procedures utilized in the 1970s and early 1980s primarily relied on radioactive probes and were quickly and preferably substituted for by fluorescence in situ hybridization (FISH) techniques that utilized nonradioactive probes labeled with haptens or fluorochromes (Manning *et al*., 1975; Pinkel *et al*., 1986). Clinical and cancer cytogeneticists readily embraced the new FISH techniques as it provided them with a way to detect complicated, cryptic, and submicroscopic rearrangements that remained undetected or undecipherable by conventional cytogenetic analysis (Kuwano *et al*., 1991; Leana-Cox *et al*., 1993; Franke *et al*., 1994; Blennow *et al*., 1994). FISH was also an attractive technique as it could be performed using both interphase nuclei and metaphase spreads (Kuo *et al*., 1991; Klever *et al*., 1992). The clinical utility of FISH in cancer cytogenetics quickly became apparent in the hematological cancers, but FISH on metaphases spreads from solid tumors was fraught with the same technical difficulties as conventional cytogenetic analysis because very few metaphase spreads are obtained after cell culture and their quality is often suboptimal. Comparative genomic hybridization (CGH), a DNA-based molecular cytogenetic technique, was developed in 1992 primarily as a way to overcome the obstacles associate with analyzing solid tissue tumors (Kallioniemi *et al*., 1992). CGH provided a very novel way to detect chromosomal

imbalances in a single-step global wide scan of the genome. Many factors made CGH an appealing technique for cancer research, the primary one being that CGH is a DNA-based technique, which therefore obviates the requirement of specimen culturing and does not have to consider the availability and quality of the specimen metaphase spreads. This property has also allowed for the analysis of formalin-fixed paraffin-embedded neoplastic tissue and even nonviable tissues, such as that derived from the products of conception. The ability to obtain a genome-wide search for imbalances without any prior information of the chromosomal aberration in question has been particularly useful in clinical cytogenetics, especially for samples for which a complete and detailed karyotype could not be obtained by conventional methods.

2. The basics of CGH

Comparative genomic hybridization (CGH) is a powerful DNA-based cytogenetic technique that allows the entire genome to be scanned for chromosomal imbalances without requiring the sample material to be mitotically active. CGH effectively reveals any DNA sequence copy number changes (i.e., gains, amplifications or losses) in a particular specimen and maps these changes on normal chromosomes (Kallioniemi *et al*., 1992; Kallioniemi *et al*., 1994). CGH can detect changes that are present in as little as 30–50% or more of the specimen cells (Kallioniemi *et al*., 1994). It does not reveal balanced translocations, inversions, and other aberrations that do not change copy number. CGH is accomplished by in situ hybridization of differentially labeled total genomic specimen DNA and normal reference DNA to normal human metaphase chromosome spreads (Kallioniemi *et al*., 1992; Kallioniemi *et al*., 1994). Hybridization of the specimen and reference DNA can be distinguished by their different fluorescent colors. The relative amounts of specimen and reference DNA hybridized at a particular chromosome position are contingent on the relative excess of those sequences in the two DNA samples and can be quantified by calculation of the ratio of their different fluorescent colors (Kallioniemi *et al*., 1992; Kallioniemi *et al*., 1994). Specimen DNA is traditionally labeled with a green fluorochrome such as fluorescein isothiocyanate (FITC) and the normal reference DNA with a red fluorochrome like Texas Red®. A gain of chromosomal material in a specimen would be detected by an elevated green:red ratio, while deletions or chromosomal losses would produce a reduced green:red ratio (Kallioniemi *et al*., 1992; Kallioniemi *et al*., 1994) (Figure 1). Computer-assisted measurement of the red:green ratio along each chromosome allows all over/underrepresented regions to be identified (Figure 1). The incorporation of standard reference intervals into the software program confers a considerably higher sensitivity to CGH analysis compared to fixed diagnostic thresholds and is often referred to as "high resolution CGH" (Kirchhoff *et al*., 1998). The sensitivity of conventional CGH is in the megabase range, with a theoretical detection limit of deletions estimated to be about 2 Mb (Piper *et al*., 1995). The introduction of high-resolution CGH has demonstrated that CGH can detect imbalances around

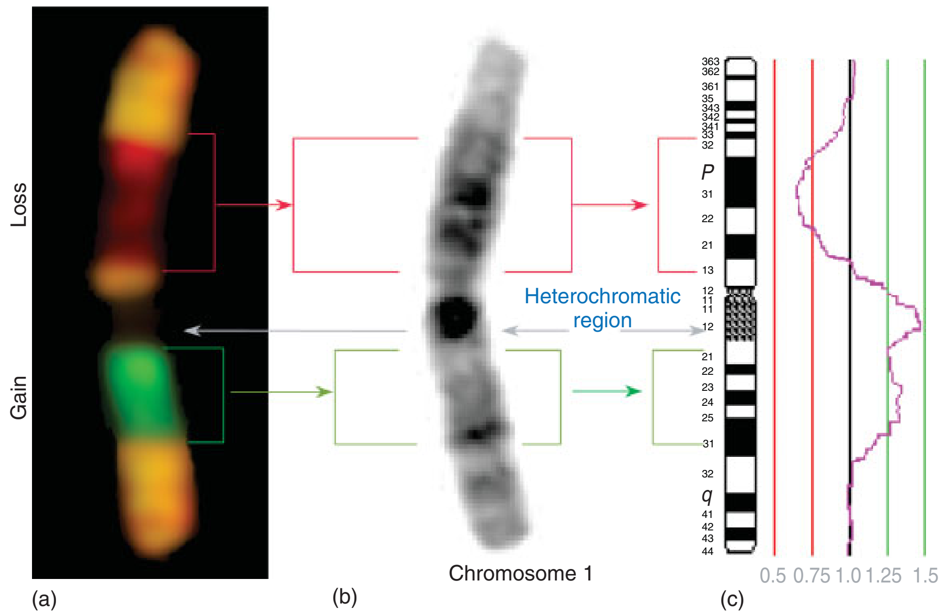

Figure 1 Mapping of chromosomal gains and losses detected by CGH. A loss in the short arm, dim (p21p31) and gain in the long arm, enh (q21q32.1) are illustrated. (a) Visual inspection of gains and losses of chromosomal material. Green regions represent a gain of specimen DNA at that region while red areas reflect greater hybridization of reference DNA at that location due to the depletion of specimen DNA. (b) Inverted DAPI image allows for identification of the chromosome. (c) Computer-generated CGH fluorescence ratio profile. The center line in the CGH profile represents the balanced state of the chromosomal copy number (ratio 1.0). Gains are viewed to the right (> 1.20) and losses (< 0.80) to the left of the center line

2–3 Mb in size (Kirchhoff *et al*., 2001), which appears comparable to that of a high-resolution karyotype (750–1000 band level).

3. Overview of CGH

The three main components of the CGH assay are the specimen DNA, the reference DNA, and the normal metaphase spreads. The specimen can be any patient sample from which DNA can be extracted. In cancer cytogenetics, this may include solid tumors and formalin-fixed preparations and in clinical cytogenetics this may include peripheral blood or prenatal samples such as chorionic villi or amniocytes. Reference DNA is extracted from karyotypically normal individuals, and the metaphase spreads are preferentially prepared from karyotypically normal 46,XY male individuals so that both the X and Y chromosomes are available as hybridization targets. Nick translation is used to label the specimen and reference (normal) DNA with different fluorochromes (usually green for the test specimen and red for the normal reference). In situ hybridization using equal amounts of labeled specimen and reference DNAs together with unlabeled Cot1-DNA is then performed using the normal 46,XY metaphase spreads. Following

this, any nonhybridized/unbound DNA is washed off and the metaphase spreads are counterstained with DAPI, which allows for chromosome identification. Fluorescence microscopy utilizing fluorochrome specific filters is required to visualize and digitally capture color ratio differences along the chromosomes. Chromosome identification is aided by the inverted DAPI banding pattern, which is similar to G-bands. Computer software quantitates the DNA copy number differences by generating a ratio profile of the specimen to reference DNA fluorescence intensities along each chromosome and is therefore critical for the actual analysis and interpretation. Combining the profiles from several metaphase spreads is necessary to improve the significance of the results.

4. CGH in cancer cytogenetics

Classical and molecular cytogenetic analysis of neoplastic specimens has produced a wealth of information regarding the hematological malignancies (Mitelman, 1994; Najfeld, 1997). In contrast, there is significantly less information known about the cytogenetics and molecular cytogenetics of solid tumors. This is mainly due to the technical difficulties encountered when preparing metaphase spreads from these tumor cells. Karyotype analysis requires viable, proliferating cells that can be arrested in the metaphase stage of the cell cycle. Since many solid tumor cells fail to proliferate in vitro, conventional cytogenetic analysis of these tumors is often not possible. For those tumors where metaphase spreads are produced, the quality is often inadequate and does not allow for recognition of banding patterns. There is also the possibility that the cytogenetic data derived from in vitro tumor cell culture is not accurate as small subclones in vivo may take advantage of the in vitro conditions, and thus, the nonproliferating cells that constitute the main clone in vivo may escape detection by conventional cytogenetic analysis (Becher *et al*., 1997). In addition, many aberrant chromosomal regions may not be identified because of the highly complex karyotypes of cultured cancer cells carrying both multiple numerical and structural chromosomal abnormalities.

Since CGH is a DNA-based analysis, initiation of a cell culture from a tumor specimen is not necessary as DNA copy number imbalances can be assessed directly from the analysis of genomic DNA extracted from these tumor specimens. The detection of chromosomal imbalances by CGH is dependent on the aberrations being present in 30–50% or more of cells from which the DNA is extracted (Kallioniemi *et al*., 1994). Therefore, the results derived using this technique reflect changes that are genuinely present in the majority of tumor cells. CGH analysis is, however, limited by its inability to provide information about balanced rearrangements, the origins of structural anomalies, or the ploidy status of the cells. Nevertheless, identification of specific regions of imbalance has been sufficient to provide a location for candidate genes (oncogenes and tumor suppressor genes) causative of the initiation and progression of these tumors.

The use of CGH in cancer genetics has revealed a number of novel recurring chromosomal gains, amplifications, losses, and deletion sites that escaped detection using traditional cytogenetic analysis in various tumors, including testicular germ

cell tumors, gliomas, sarcomas, breast cancer, prostate cancer, uterine leiomyomata, small-cell lung carcinoma, head, neck and pancreatic carcinomas, and uveal melanomas. The chromosomal aberrations detected by CGH has also provided prognostic information in a number of neoplasms including esophageal squamous cell carcinoma, renal cell carcinomas, breast carcinomas, cervical carcinomas, endometrioid carcinoma, malignant fibrous histiocytoma, neuroblastoma, bladder cancer, uveal melanoma, and prostate cancer. Various international CGH databases have been established that provide a wealth of information on the CGH studies that have been done since 1992 including the Progenetix cytogenetic on-line database (**http://www.progenetix.net**), the Tokyo Medical and Dental University CGH database (**http://www.cghtmd.jp/cghdatabase/index_e.html**), the database of Humboldt-University of Berlin (**http://amba.charite.de/~ksch/cghdatabase/index.htm**) and the National Cancer Institute and National Center for Biotechnology Information Spectral Karyotyping SKY, and Comparative Genomic Hybridization CGH Database (2001), (**http://www.ncbi.nlm.nih.gov/sky**). The use of CGH in cancer cytogenetics has now led to the discovery of new tumor suppressor genes and oncogenes that play a role in the initiation and/or progression of solid tumors and has therefore laid the groundwork for the development of appropriate and tissue-specific therapeutic agents.

5. CGH in clinical cytogenetics

Clinical cytogenetics in the late 1990s realized that the powerful genome-wide scanning attribute of CGH could be used to identify karyotypes with unbalanced or unrecognizable G-banded cytogenetic material (Bryndorf *et al*., 1995; Levy *et al*., 1998). This was an exciting application of the relatively new molecular cytogenetic technique as it could more precisely characterize the regions of imbalance in patients with chromosomal abnormalities, and thus pave the way for discovery of the gene(s) that are responsible for the clinical features observed in such patients. In the past, identification of unbalanced cytogenetic material of unknown origin required a comprehensive molecular cytogenetic work-up using various FISH probes. This approach is both expensive and labor intensive as numerous probes and/or whole-chromosome paints may be required until the origin of the chromosomal material is identified. In addition, the number of commercially available region-specific probes is limited and covers only a fraction of the genome. CGH also has the advantage over conventional FISH with whole chromosome paints (wcps) and multicolor FISH by its ability to identify not only the chromosome from which the extra unknown material originated but also to map the region involved to specific G-bands on the source chromosome. In addition, the CGH analysis does not require any prior information of the chromosomal imbalance in question as it scans the entire genome in a single step. The DNA-based nature of CGH also allows for the analysis of specimens that have failed to grow in cell culture (Fritz *et al*., 2001). This has been especially effective in the analysis of spontaneous abortions, which are estimated to have a chromosome abnormality (mainly aneuploidy) approximately 50–70% of the time (Fritz *et al*., 2001; Gardner and Sutherland, 2004).

To date, more than 1800 articles have been published on CGH with the most reporting the utility of CGH to identify novel chromosomal imbalances in neoplastic specimens (**http://www.ncbi.nlm.nih.gov:80/entrez/query.fcgi?**). Less that 10% of CGH papers have dealt with technical aspects and only a limited number have described the application of CGH in a clinical cytogenetics setting. CGH has been shown to be a valuable tool in clinical cytogenetics by allowing for the characterization, in a single hybridization, of deletions, intrachromosomal duplications, unbalanced translocations, and marker chromosomes, including neocentric marker chromosomes (Kirchhoff *et al*., 2001; Levy *et al*., 1998; Levy *et al*., 2000). Various CGH studies have provided clinical correlation between specific chromosomal regions of imbalance and various clinical entities such as the duplication 5q phenotype (Levy *et al*., 2002) and partial tetrasomy 10p which resulted from an analphoid marker chromosome with a neocentromere (Levy *et al*., 2000). Such studies have helped to further define critical chromosomal regions, which are associated with normal and adverse phenotypic outcomes (Levy *et al*., 2000; Levy *et al*., 2002) thus providing prognostic information for genetic counseling. This type of information benefits prenatally ascertained cases of marker chromosomes as it may provide couples with a means to make rational and informed decisions concerning the pregnancy. In pediatric cases, such information may provide the parents with a realistic prognosis and will be important for the clinical management of the infant.

6. CGH in preimplantation genetic diagnosis

Molecular cytogenetic analyses of human preimplantation embryo have revealed extremely high levels of chromosomal abnormality (Munne *et al*., 1993; Delhanty *et al*., 1997). Upwards of 70% of abnormally developing embryos show chromosome abnormalities and mosaicism (Munne *et al*., 1993; Delhanty *et al*., 1997). Many women referred for in vitro fertilization (IVF) are of advanced maternal age, with an elevated risk for conceiving and delivering a child with chromosome aneuploidies. The rate of aneuploidy (approximately 40%) in normally developing embryos from older women (>40 years) is about 10 times higher than the incidence of aneuploidies (4%) in embryos from younger women (20–34 years) (Munne *et al*., 1995). The presence of aneuploidy impacts directly on the success of implantation, which is also one reason why embryos from older women are subject to higher implantation failure rates (Munne *et al*., 1995; Gianaroli *et al*., 1997; Munne *et al*., 1999). Current preimplantation genetic diagnosis (PGD) aneuploidy is carried out via multicolor FISH on interphase blastomeres and typically includes screening for chromosomes 13, 16, 18, 21, 22, X and Y (Munne *et al*., 1998). The ability to screen for additional aneuploidies is hampered by the number of chromosome-specific probes that can be used per hybridization. The power of CGH to detect total aneuploidy makes it an appealing diagnostic tool for use in preimplantation genetic diagnosis (PGD) as the selective transfer of diploid embryos would presumably result in higher implantation rates as well as lower miscarriage rates (Wilton *et al*., 2001; Wells *et al*., 2002; Wells and Levy,

2003). Various investigators have demonstrated that CGH can detect aneuploidy and partial aneuploidy as small as 3 MB in a clinical setting (Levy *et al*., 1998; Kirchhoff *et al*., 1999). Since the smallest autosome is in excess of 50 MB, CGH analysis provides a very powerful and sensitive method for PGD detection of whole chromosome aneuploidy and a few studies have now effectively demonstrated this in polar bodies and preimplantation embryos (Wilton *et al*., 2001; Wells *et al*., 2002; Wells and Delhanty, 2000). The major stumbling block in this application is the technical difficulties associated with reliably amplifying the DNA from a single cell so that sufficient DNA is available for the CGH analysis. Newer whole genome amplification methodologies may provide a robust way for a CGH-type analysis to become an integral part of PGD for aneuploidy.

7. Conclusion

Comparative genomic hybridization permits detailed cytogenetic data to be obtained from a wide range of tissues not usually amenable to analysis by conventional cytogenetic methods. These include formalin-fixed neoplastic specimens, freshly obtained solid tumors, mitotically inactive cells derived from products of conception, and single cells biopsied from polar bodies and preimplantation embryos. As a cancer research tool, CGH has proven invaluable for the ascertainment of chromosomal duplications, amplifications, and deletions that contain critical genes, which contribute to the neoplastic transformation of a whole battery of tissues. The application of CGH to prenatal and pediatric samples has also proven extremely beneficial, allowing the delineation of complex or cryptic chromosomal rearrangements that could not be defined using classical cytogenetic techniques. The use of CGH as a tool for PGD may allow for the detection and preferential transfer of the embryos most likely to form a viable pregnancy and thus lead to improvements in the outcome of assisted reproductive procedures.

CGH methodology is currently evolving as chromosomal targets are being replaced by arrays consisting of genomic clones, which are spotted onto glass microscope slides (Pinkel *et al*., 1998). These technical advances allow for the detection of much smaller imbalances (100–200 kb), such as those observed in the Digeorge and Prader–Willi syndromes (Pinkel *et al*., 1998). Current arrays have genomic coverage spaced about 1 Mb apart, and ongoing efforts are being made by researchers to create tiled arrays that span the entire genome. This technology remains expensive and will likely not be a common finding in all cytogenetics laboratories for a good few years. The use of regular CGH for the time being still remains an attractive and powerful accessory to routine clinical cytogenetic analysis.

Cytogenetic analysis of lymphomas

Douglas E. Horsman
British Columbia Cancer Agency, Vancouver, BC, Canada

1. Introduction

Historically, the application of cytogenetic analysis to the investigation of malignant lymphoma has provided the entry point for the identification of critical gene deregulations associated with specific subtypes of B- and T-cell malignant lymphomas (*see* Article 14, **Acquired chromosome abnormalities: the cytogenetics of cancer**, Volume 1). These include the IGH-MYC gene fusion created by the t(8;14)(q24;q32) of Burkitt leukemia/lymphoma, the IGH-CCND1 fusion resulting from the t(11;14)(q13;q32) of mantle cell lymphoma, and the IGH-BCL2 fusion associated with the t(14;18)(q32;q21) of follicular lymphoma and the BCL6 translocations found in diffuse large cell lymphomas, as well as other less common examples. This important cancer genetic information has been accessible to laboratory investigation due to the relative ease with which tissue specimens can be obtained from patients affected by these diseases and the ability to successfully propagate these cell samples in vitro, allowing examination of the chromosomal makeup of the malignant cells. The investigation of malignant lymphoma karyotypes continues to have important research implications, with a shifting of emphasis away from the well-defined primary alterations mentioned above to a scrutiny of the secondary chromosomal changes that characterize clonal expansion and disease evolution. These secondary changes may have an important role in determining the pace of disease progression or the transformation of low-grade disease to a more aggressive type of disease. At the clinical level, the detection of disease-specific changes may be of great help to the pathologist and oncologist to determine the proper diagnosis and to detect important prognostic or predictive factors that will aid in treatment planning and disease follow-up. The importance of genetic analysis in the assessment of malignant haematopoietic disorders has been emphasized in the most recent version of the World Health Organization Classification of Tumours: Pathology and Genetics of Haematopoietic and Lymphoid Tissues (2001).

The successful application of cytogenetic analysis to malignant lymphoma specimens is predicated on appropriate sampling of representative diseased tissue from the patient. The specimen must be transported to the lab in a viable condition, followed by optimal culturing, harvesting, slide making, chromosome

banding, and microscopic analysis to allow the identification of cell divisions or metaphases that are representative of the clonal population within the tissue sample. Numerous technical resources are available that describe the theoretical and technical basis of cytogenetic analysis of constitutional and cancer cell specimens as well as the standard nomenclature that is used in clinical practice for the description of normal and altered chromosome morphology. For these types of information, the interested reader is referred to the ACT Cytogenetic Laboratory Manual (1991) and the International System of Cytogenetic Nomenclature (ISCN, 1995) and other pertinent references (Therman, 1986; Verma and Babu, 1995). An in-depth description of the application of cytogenetic analysis to cancer specimens and the types of alterations found in various types of cancer, including malignant lymphoma, has been written by Heim and Mitelman (1995). In addition, a number of useful websites are available that can be accessed to search for chromosomal alterations associated with various types of cancer. These include the Atlas of Genetics and Cytogenetics in Oncology and Haematology (**http://babbage.infobiogen.fr/services/chromcancer/index.html**) and the Mitelman Database of Chromosome Aberrations in Cancer (**http://cgap.nci.nih.gov/Chromosomes/Mitelman**). Information on the description and classification of malignant lymphomas is provided in the World Health Organization Classification of Tumours: Pathology and Genetics of Haematopoietic and Lymphoid Tissues (2001).

2. Specimen collection and transport

The source of clinical specimens for cytogenetic analysis includes any tissue or fluid that may contain infiltrates of malignant lymphoma cells, such as lymph node biopsies, marrow aspirates, peripheral blood samples, fine needle aspirates, and fluids obtained from body cavities. Appropriate aseptic technique should be followed during specimen acquisition. The specimen may be sent directly to the laboratory, or placed in a minimal essential media (i.e., RPMI 1640) to ensure the preservation of viability during transit to the laboratory. The specimens should be kept cool, possibly in a 4°C refrigerator or on ice, with precautions taken to prevent freezing. Upon receipt in the laboratory, triage of the specimen to other investigations such as immunophenotyping and morphology examination may be appropriate, that is, for lymph nodes and marrow aspirates, or the entire specimen may be utilized for cytogenetic analysis if other investigations are not required. Histologic, cytologic, or immunophenotypic evaluation of a portion of the specimen may be helpful in confirming that the malignant cells are represented in the sample that has been submitted for cytogenetic analysis.

3. Culture and harvest, slide making, and chromosome banding

Solid specimens such as lymph node biopsies should be subjected to disaggregation by gentle mincing and vortexing in culture media or saline solution to obtain a

single cell suspension. Such cell suspensions, including aspirate or fluid specimens, are most suitable for the culture procedure. The standard methods used for leukemia specimens have proven successful for malignant lymphoma. A 24-h culture in a minimal essential media such as RPMI 1640 with the addition of fetal calf serum and glutamine supplement is normally used. Other growth stimulants or mitogenic agents are generally not required or recommended. In certain disease subtypes where the proliferation rate is extremely low, or when the clonal cells are sensitive to apoptosis in vitro, the use of growth stimulants may be helpful to obtain metaphases; however, such conditions or agents may induce selective growth of normal cells or subpopulations of the malignant cell population, thus rendering bias into the subsequent karyotype interpretation.

Harvesting of the cultured cells, the making of slides to obtain metaphase spreads and the banding of the chromosomes should be undertaken using standard approaches that have been adapted to local laboratory conditions and the experience of the practitioners (*see* Article 12, **The visualization of chromosomes**, Volume 1). A variety of banding techniques, including Q-, G-, and R-banding have been utilized, with equal success for the interpretation of numerical and structural chromosomal alterations associated with lymphoma. When possible, the documentation of both normal and abnormal metaphases from the specimen should be sought, the former to ensure that possible inherited chromosomal alterations in normal cells are not misinterpreted to represent acquired, lymphoma-related alterations.

4. Metaphase analysis

The great majority of malignant lymphomas will show clonal karyotypic alterations, with some notable exceptions, such as chronic lymphocytic leukemia where the clonal cells are sensitive to apoptosis in vitro, rendering the identification of clonal metaphases difficult, and in Hodgkin disease, where the proportion of malignant cells in the specimen represents a small minority of the total cell population and obtaining metaphases from these malignant cells is notoriously difficult, requiring the use of molecular methods to detect possible chromosome rearrangements and dosage alterations. In most lymphoma subtypes, however, a clonal karyotype will be evident with the analysis of 10 to 20 metaphases. The complexity of the karyotypes may vary from simple whole-chromosome gains or losses such as +3 or −13, single balanced translocations such as t(8;14)(q24;q32), to more complex karyotypes with a combination of chromosomal numerical and structural alterations including balanced and unbalanced translocations, inversions, insertions, deletions, duplications, and the presence of complex derivative chromosomes called marker or ring chromosomes or chromosomal additions where the origin of the extra chromosomal material cannot be ascertained from the evident banding pattern (see Figure 1) (*see* Article 11, **Human cytogenetics and human chromosome abnormalities**, Volume 1). The description of the karyotypic changes should conform to the guidelines outlined in the International System of Cytogenetic Nomenclature (ISCN, 1995). In certain situations, the short-form description for observed chromosome alterations may not be sufficient to accurately describe

Figure 1 A G-banded karyotype of a representative case of malignant lymphoma with a primary chromosomal translocation t(14;18)(q32;q21) (arrows point to the derivative 14 and 18 chromosomes) and a single secondary change consisting of an extra copy of chromosome 12 (arrow)

the evident changes, and the more detailed, long-form description of individual derivative chromosomes may be required.

Most lymphoma karyotypes are in the near-diploid to hyperdiploid range, with polyploidy karyotypes being found in a minority of cases. These polyploid karyotypes may be in the near-triploid to near-tetraploid chromosome complement range, and are seldom, if ever, balanced. Single unique stemlines may be identified, but closely related sidelines are often evident if sufficient metaphases are examined. Such sidelines most commonly represent the result of sequential or divergent evolution of the clonal karyotype, with preservation of preexisting stemline changes in the evolved sidelines. Occasionally, independent clones may be identified with no shared alteration that links them to a common precursor stemline. These may harbor subcytogenetic alterations that link them to a common stemline or they may truly represent multiclonal proliferations. In some cases, there is a marked variation between sidelines and even between individual metaphases, and such heterogeneity being indicative of an extreme level of genetic instability.

5. Clinical indications for cytogenetic studies

The clinical utility of a full karyotype analysis of a malignant lymphoma should be determined by the need for such information to assist in patient management or follow-up. A partial list of disease-specific chromosomal alterations that have been detected in malignant lymphoma is provided in Table 1. Interpretation of chromosomal alterations in lymphoma specimens should always be undertaken in conjunction with information obtained from the morphologic and phenotypic evaluation of the specimen and with knowledge of the clinical situation that initiated the investigation. The necessity for chromosomal data in malignant lymphoma has not yet reached the level of importance that is assumed for the leukemias, and

Table 1 Chromosomal translocations associated with specific subtypes of malignant lymphoma

Chromosome alteration	Gene alteration	Disease subtype
t(8;14)(q24;q32)	IGH-MYC	Burkitt lymphoma
t(11;14)(q13;q21)	IGH-CCND1	Mantle cell lymphoma
t(14;18)(q32;q21)	IGH-BCL2	Follicular lymphoma
t(3;14)(q27;q32)	IGH-BCL6	Diffuse large cell lymphoma
t(11;18)(q21;q32)	API1-MALT1	Extranodal marginal zone lymphoma
del(7q) or dup(3q)	Not known	Splenic marginal zone lymphoma
t(2;5)(p23;q35)	ALK-NPM	Anaplastic large cell lymphoma
+3, +15, +X	Not known	Angioimmunoblastic lymphadenopathy
del(9q34-34)	Not known	Enteropathy-associated T-cell lymphoma
dup(7q)	Not known	Hepatosplenic gamma/delta T-cell lymphoma

in many situations surrogate information obtained by immunophenotyping may be adequate to infer the presence of an underlying chromosomal alteration. Currently, a number of clinically useful indications for chromosome analysis can be cited, including the differential diagnosis of Burkitt leukemia/lymphoma from other high-grade lymphomas, the identification of ALK translocations in anaplastic large cell lymphomas, and the differential diagnosis of mantle cell lymphoma from atypical forms of chronic lymphocytic leukemia or other low-grade lymphoproliferative disorders. The diagnosis and management of the common forms of follicular lymphoma and diffuse large cell lymphoma does not routinely require chromosomal information. However, as more information on the prognostic influence of BCL6 rearrangements and other gene deregulations becomes established, methods to obtain objective information on these genetic factors may be required to assist in the clinical management of a larger proportion of lymphoma patients. For many indications, the availability of fluorescence in situ hybridization (FISH) probes to detect specific chromosomal changes has supplanted the need for full karyotypic analysis (Siebert and Weber-Matthiesen, 1997). This is exemplified in chronic lymphocytic leukemia, where it has been demonstrated that prognostic subgroups can be identified on the basis of the presence or absence of trisomy 12 and deletion of 11q22, 17p13, and 13q14. This type of multigene assessment is best undertaken by FISH analysis using specific DNA probes for the chromosomal region or genes involved, owing to the difficulty in obtaining metaphases from chronic lymphocytic leukemia samples and the often cryptic nature of the deletions affecting these sites.

6. Supplemental molecular cytogenetics

In situations in which the exact chromosomal composition of certain abnormal chromosomes cannot be confidently determined by the chromosomal banding pattern, verification can be obtained through the application of appropriate FISH techniques, using chromosome centromere-specific probes, locus-specific probes, chromosome painting probes and multicolor karyotyping reagents (*see* Article 22, **FISH**, Volume 1). Such FISH techniques can be applied to a variety of cell sources, including imprints made from biopsy specimens, air-dried cell suspensions

or smears (i.e., from blood, marrow or fluid samples), from the methanol-acetic acid cells pellets remaining from the specimen used for karyotype analysis, and also from frozen or fixed tissue. Of particular importance is the ability to use tissue samples that have been preserved in formalin and embedded in paraffin for histological interpretation. These samples can be used either as paraffin sections mounted on glass slides, or as disaggregated nuclei obtained by dissection from the paraffin block, targeting specific areas in the block to ensure appropriate representation of the disease in the sample. A particularly useful approach in this regard is a tissue array coring device, which can be used to sample 0.5- or 1-mm cores of paraffin-embedded tissue, selected on the basis of an H&E slide sectioned from the same block. The core or section of tissue must be subjected to appropriate deparaffinization and pretreatment prior to hybridization with the DNA probe.

7. Types of FISH probes for malignant lymphoma investigation

Locus-specific FISH: a variety of probes are available from commercial sources, such as Vysis Inc. that have been developed and optimized for specific lymphoma translocation or rearrangement analysis, such as MYC, BCL6, t(8;14), t(11;14), t(14;18), and ALK. The dual-color split-apart probes are particularly useful for the

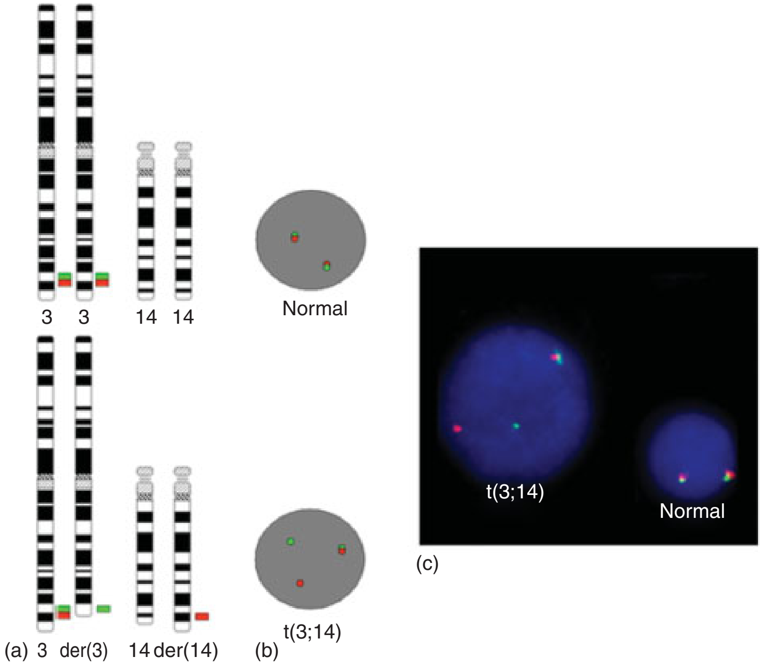

Figure 2 The hybridization patterns produced by a dual-color split-apart FISH probe used to detect BCL6 translocations in malignant lymphoma. The normal gene configuration shows two red-green fusion signals in each normal nucleus. A malignant cell nucleus with a BCL6 translocation such as t(3;14) shows one red, one green, and one fusion signal

interrogation of the configuration of an individual gene when multiple translocation partners have been identified, such as for BCL6 and ALK (see Figure 2). The MYC probe may be helpful in determining the possible presence of variant translocations not detected by the t(8;14) probe. Similarly, probing with a BCL2 probe may be necessary to detect variant translocations associated with follicular lymphoma, since commercial sources of the kappa and lambda immunoglobulin gene probes are not currently available to detect IGL-BCL2 translocations. Dual color, dual fusion probes are particularly useful for the detection of chromosomal translocations associated with Burkitt leukemia/lymphoma, follicular lymphoma, or mantle cell lymphoma (see Figure 3). Variant translocation signal patterns may be obtained in some cases, because of associated deletions and duplications, rendering interpretation difficult. In these situations, the availability of metaphases in the preparation may help resolve the interpretation of the signal pattern, where the signal localizations on individual chromosomes can be determined from the reverse

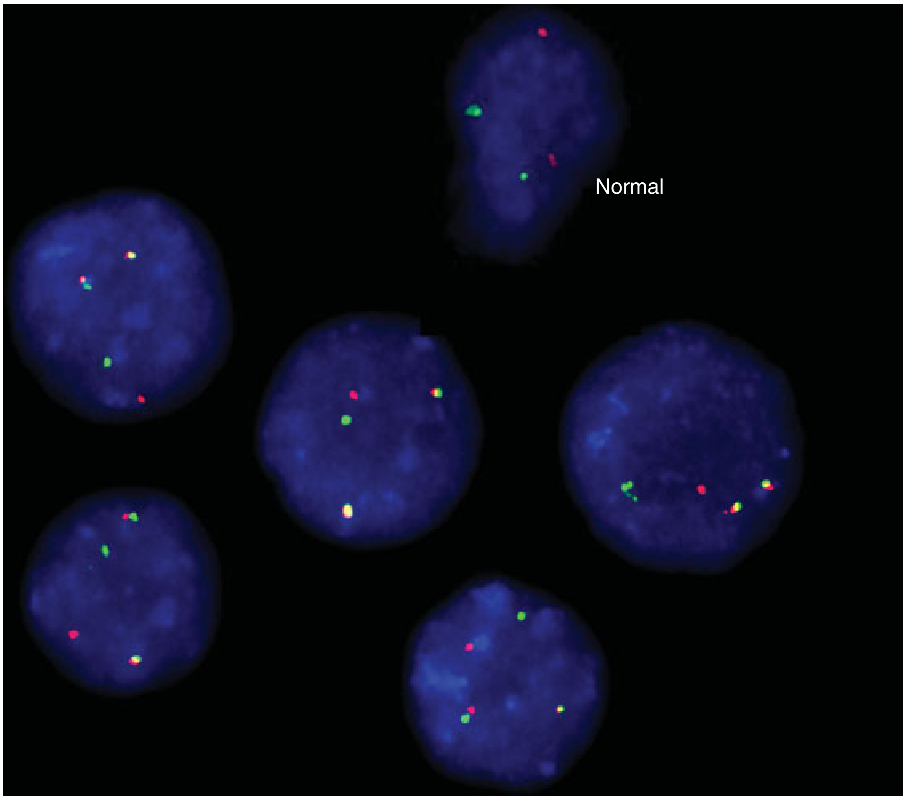

Figure 3 The hybridization patterns found with a dual color, dual fusion translocation FISH probe used to detect translocations such as the t(11;14)(q13;q32) in malignant lymphoma. The normal gene configuration shows two red and two green signals in each nucleus, indicating the two copies each of the IGH and CCND1 genes in normal nuclei. A nucleus with a t(11;14) shows one red, one green, and two fusion signals, indicating the presence of IGH-CCND1 fusions

banding pattern on the chromosomes resulting from the DAPI (4′-6′-diamidino-2′-phenylindole) staining, or by comparing to G-banded metaphases if these are also available. If only interphase nuclei are available, such as from paraffin-embedded tissue, an accurate interpretation of atypical signal patterns may not be possible.

Currently, there are a limited number of probes available for malignant lymphoma investigation, although additional commercial probes are continually being developed and marketed. Alternatively, readily available bacterial artificial chromosomes (BACs) or other vector constructs containing known fragments of human DNA can be obtained for preparation of "in house" or "home brew" FISH probes. Appropriate propagation, purification, labeling, and validation of the probe with local positive and negative controls is required prior to the utilization of such probes for clinical purposes. Protocols are available through organizations such as the National Committee for Clinical Laboratory Standards (NCCLS) (**http://www.nccls.org/**) to guide the preparation and validation of such probes.

Multicolor Karyotyping: The development of multicolor chromosome painting techniques, including the so-called SKY and MFISH methods (Schrock *et al*., 1996; Speicher *et al*., 1996), have provided the capability to more accurately

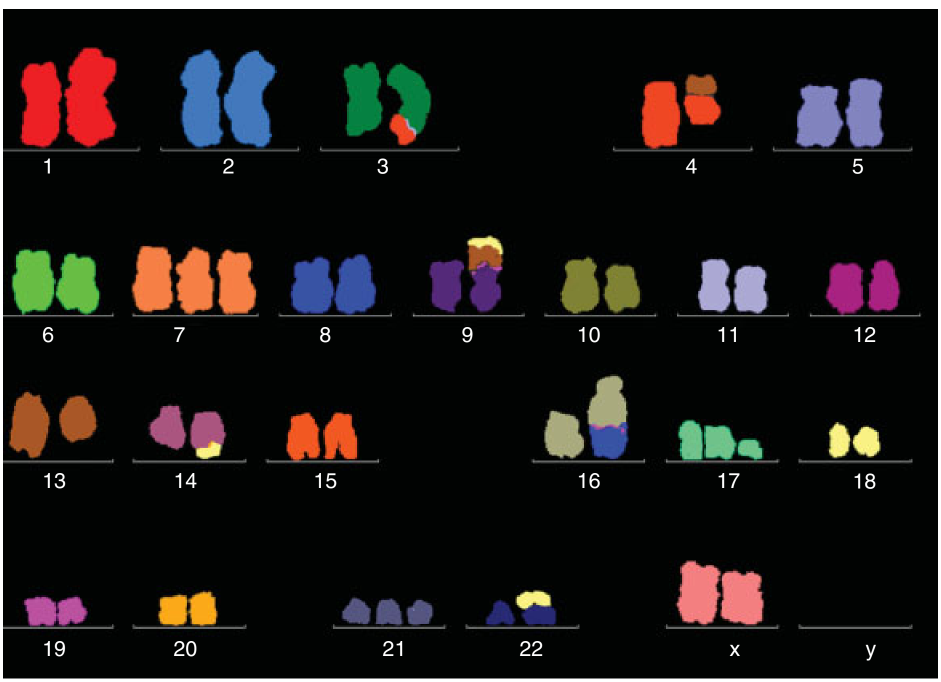

Figure 4 MFISH image of a complex lymphoma karyotype using the Metasystems MFISH reagent. Each chromosome is identified by a unique assigned color based on a unique fluorescence signal. The karyotype contains a t(14;18) with only the derivative chromosome 14 apparent, as the small portion of chromosome 14 that is translocated to chromosome 18 cannot be visualized with this reagent. Additional secondary chromosome changes are evident, including an extra whole chromosome 7 and 21, an additional partial chromosome 17, unbalanced translocations between 3 and 4, 4 and 13, 16 and 8, and 22 and 18, and a more complex derivative 9 containing material from chromosomes 9, 13, and 18

define complex chromosomal changes that have defied interpretation by standard chromosome banding methods. In particular, it has allowed the deciphering of the chromosomal makeup of marker chromosomes and ring chromosomes, and chromosomal additions were the small pieces of extra chromatin that cannot be identified by chromosomes banding methods. The application of these reagents has shown that many marker and derivative chromosomes are made up of multiple segments of material from different chromosomal sources (see Figure 4). In some situations, the regional source of this material can be deduced from the chromosome banding pattern, but if the segment is small, it may not be possible to determine whether it comes from the p or q arm of the donating chromosome. In these situations, additional verification using locus specific probes or multicolor banding reagents (see Figure 5) (Chudoba *et al*., 1999) may be required to fully ascertain the identity of the chromosomal segments within these complex rearranged chromosomes.

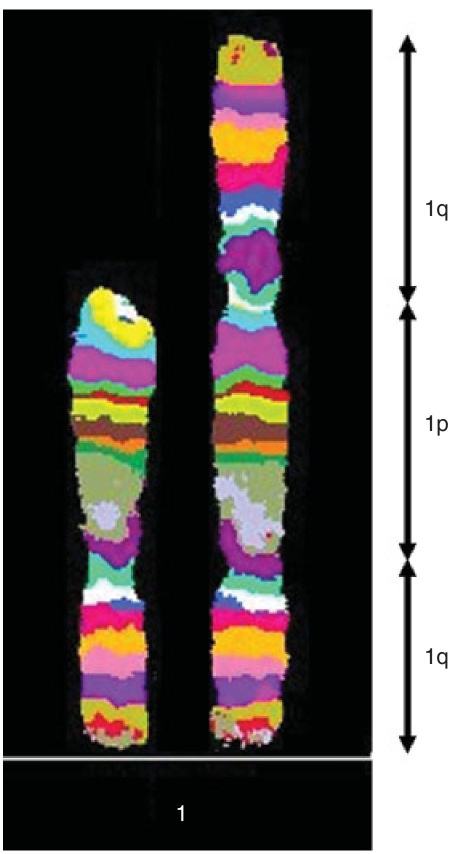

Figure 5 Multicolor banding of chromosome 1 using the Metasystems MBAND1 probe reagent. The two chromosomes on the left depict normal copies of chromosome 1. The two chromosomes on the right display a large regional duplication of the q arm of chromosome 1

Acknowledgments

I would like to thank the cytogenetic technologists of the BC Cancer Agency for the provision of the images for Figures 1, 2, and 3, Dr. Valia Lestou for the images for Figures 4 and 5, and Ms. Chris Salski for proofreading of the manuscript.

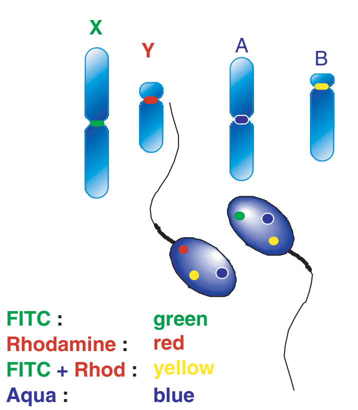
Human sperm–FISH for identifying potential paternal risk factors for chromosomally abnormal reproductive outcomes

Andrew J. Wyrobek, Thomas E. Schmid and Francesco Marchetti
University of California, Livermore, CA, USA

1. Introduction

A substantial challenge in the identification of human germ cell mutagens is to classify offspring carrying inherited genetic defects, to identify the responsible parent who transmitted the defect, and to determine whether specific genetic defects were caused by prefertilization exposure to environmental, occupational, medical, or other agents. The relatively large baseline frequencies of abnormal reproductive outcomes among human beings contribute to this problem. Every year in the United States, more than 20 million conceptions are lost before the 20th week of gestation and among these, about 50% carry numerical or structural chromosomal defects (McFadden and Friedman, 1997). Chromosomally defective offspring who survive to birth are at higher risks of malformations and other negative health effects (Jacobs, 1992). There is growing evidence that a substantial fraction of chromosomal defects, especially structural aberrations, are transmitted by the sperm (Robbins *et al*., 1997), pointing to the need for effective sperm assays for transmissible genetic damage. However, the sperm nucleus presents an unusual biophysical challenge. It is very dense with highly cross-linked chromatin, making it difficult to assess its chromosomal content.



Rudak *et al*. (1978), working in the Yanagamachi laboratory in Hawaii, developed one of the first direct methods for analyzing human-sperm chromosomes (human-sperm/hamster-egg cytogenetic method, or hamster-egg method for short) (review by Brandriff *et al*., 1994; *see also* Article 12, **The visualization of chromosomes**, Volume 1). Using this method, human-sperm chromosomes can be examined by conventional cytogenetic staining at the first metaphase after fusing capacitated human sperm with enzymatically denuded hamster oocytes. This highly efficient matchup has not been equaled using gametes from other species. The hamster-egg system showed that sperm of normal men are about 2% aneuploid

with 2–7% having chromosomal structural aberrations, and that certain cancer therapies induced higher frequencies of chromosomally abnormal sperm (review by Brandriff *et al*., 1994). However, this technique is very labor-intensive; only a handful of laboratories ever mastered it, and no recent publication has utilized it.

2. Sperm-FISH assay

In the late 1980s, fluorescence in situ hybridization (FISH) (*see* Article 22, **FISH**, Volume 1) technology was adapted for the detection of chromosomally defective sperm (e.g., Wyrobek *et al*., 1990). It is an extremely simple procedure, compared to the hamster technique. Briefly, semen is smeared onto glass slides and sperm chromatin is decondensed (e.g., by dithiothreitol) so that fluorescently labeled chromosome-region-specific DNA-probes can penetrate the chromatin to hybridize to the target region in the sperm nucleus (Figure 1).

A variety of human sperm-FISH assays have been developed for detecting aneuploidy (Figure 1). Combinations of up to four chromosome-specific DNA-probes are each labeled with a different fluorescent color. Individual sperm are also marked with a DNA dye (such as DAPI) to identify the nucleus, and the number of specifically colored fluorescent domains within the nucleus are counted under the fluorescence microscope. Sperm with two domains of the same color are assumed to be disomic, while sperm lacking the same domain are assumed to be nullisomic for that chromosome. Controlling of technical factors is critical for the reliability of the sperm-FISH assay, especially when small changes are expected between exposed and control groups (Schmid *et al*., 2001). Comparisons between different laboratories have demonstrated the importance of training, harmonizing scoring criteria, and rigorously blinding scorers. More recently, a sperm-FISH technique was developed (ACM assay) to detect sperm carrying structural as well as numerical chromosomal abnormalities, as illustrated in Figure 2 (Sloter *et al*., 2000). The ACM FISH assay uses DNA-probes specific for three regions of chromosome 1 to detect human sperm that carry numerical chromosomal abnormalities plus two

Sperm genotype →	Syndrome/loss
Sex chromosomes	
X - Y	**X-X-Y,** Klinefelter
X - X	**X-X-X**
Y - Y	**X-Y-Y**
0	**X-0,** Turner
Autosomal disomy	
8 - 8	Early loss
16 - 16	Spont. abortion
13 - 13	Patau
18 - 18	Edwards
21 - 21	Down

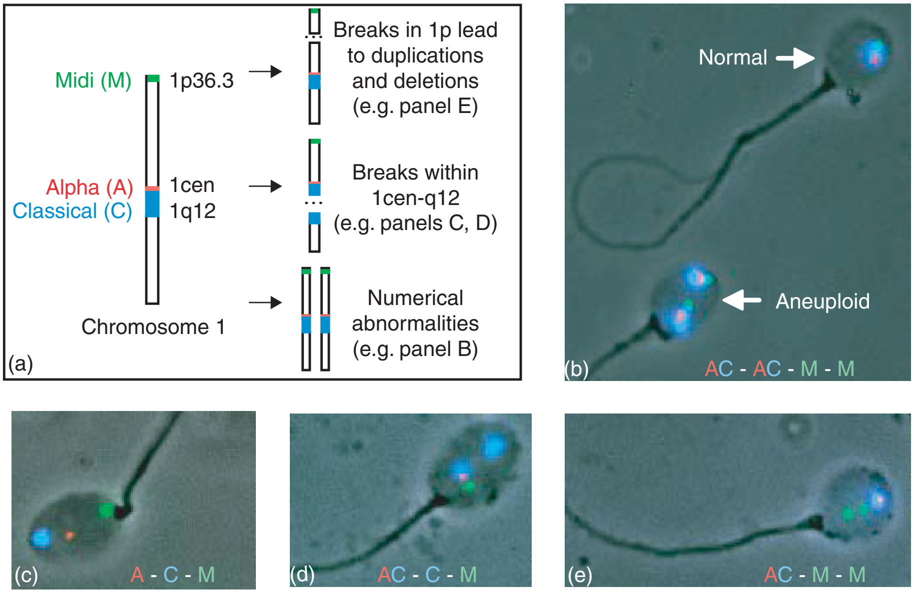

Figure 2 ACM human sperm–FISH for detecting sperm carrying either numerical or structural chromosomal abnormalities

categories of structural aberrations: duplications and deletions of 1pter and 1cen, and chromosomal breaks within the 1cen-1q12 region.

3. Advantages of the sperm-FISH assay

Sperm-FISH methods are gaining in popularity for assessing the effects of exposures because of their relative ease in collecting data when compared with epidemiological studies of human offspring, animal breeding studies, or the hamster technique (Brandriff *et al*., 1994). Compared to the hamster-egg method, which required fresh samples, sperm-FISH can utilize frozen semen specimens (for example, sperm-FISH has been effective for sperm stored for over 20 years). In addition, sperm-FISH requires much less scoring time allowing the analyses of 10 000 sperm and more per sample compared to 10–100 sperm typically scored by the hamster-egg method. The advantage of analyzing large numbers of sperm in a relatively short amount of time by sperm-FISH confers a relatively high level of sensitivity and statistical power to these assays, so that small increases can be detected by analyzing sperm from a small number of donors per experimental group. Table 1 shows the baseline variations for sperm aneuploidy and aberrations using data from the ACM assay in a group of young healthy men. Structural chromosomal abnormalities occur at higher frequencies than numerical abnormalities, while breaks are more prevalent than partial duplications and deletions. Men can vary significantly in their baseline frequencies for specific classes of chromosomally abnormal sperm, and these differences can persist over years affecting aneuploidy in both sperm and blood (Rubes *et al*., 1998).

Table 1 Chromosomally abnormal sperm detected by ACM human sperm–FISH: baseline frequencies among healthy individuals and the statistical sample size requirements for detecting increases in frequencies after toxicant exposure and varying lifestyle factors

Categories of sperm chromosomal defects detected by ACM sperm-FISH	Baseline frequencies[a]	Sample size to detect percentage increase or decrease[b]	
		50%	100%
Segmental aneuploidies			
1 pter duplication	6.4 ± 3.1	20	5
1 pter deletion	4.4 ± 4.7	96	24
Total	10.8 ± 5.5	22	6
1 cen-1q12 duplication	1.0 ± 1.3	143	36
1 cen-1q12 deletion	0.8 ± 1.4	258	65
Total	1.8 ± 1.6	67	17
Chromosomal breaks			
Between 1cen and 1q12	1.5 ± 1.7	108	27
Within 1q12	3.1 ± 2.3	47	12
Total	4.6 ± 3.2	41	10
Disomy and diploidy			
Disomy 1 or diploidy	22.7 ± 11.2	21	6

[a]Per 10 000 sperm: Mean + SD of 10 men (20–30 years of age, nonsmokers).
[b]Sample size = number of men needed per group; equal number of exposed and controls so that the total number of men for a comparison study would be twice that shown (10 000 sperm per sample).

Sperm-FISH provides a promising approach to identifying potentially damaging host factors and exposures that may increase the production of chromosomally defective sperm. Understanding these risk factors would help us design better epidemiological investigations of paternally transmitted abnormal reproductive outcomes. Table 1 provides statistical estimates of the sample size requirements to detect induced increases of 50 or 100% over baseline frequencies in the normal population. These sample sizes are dependent on the means and variances in the normal population and on the expected increase and variances among the exposed. The rarer the abnormality among normal men, the higher is the number of donors needed per group to detect an induced effect. In general, a doubling of the frequencies of chromosomally defective sperm can be detected with a sample size of about 10 men per group (range 6 to 65 for various subtypes of damage, Table 1). Sperm-FISH has already identified several risk factors and exposures that may increase the frequencies of sperm with chromosomal abnormalities (Table 2), including lifestyle, medical drugs, and occupational exposures.

4. Interspecies applications and challenges of sperm-FISH

Sperm-FISH has the intrinsic advantage of being equally applicable to any laboratory and domestic species (Lowe *et al*., 1996; Lowe *et al*., 1998; Hill *et al*., 2003). Rodent sperm–FISH may provide a platform for systematic tests of the genetic damage to germ cells of the myriads of chemicals present in the environment, and

for prioritizing human epidemiological studies of paternally mediated abnormal reproductive outcomes. The main limitation for developing a sperm-FISH assay in any new species is the availability of reliable chromosome-region-specific DNA-probes for that species. For humans, probes are now commercially available for all chromosomes. Also, as the interest in sperm-FISH across species continues it will be possible, for the first time, to compare the sperm response among species and to select the best animal model for screening for human male germ cell mutagens.

The new sperm-FISH assay for structural aberrations also provides a direct approach to identify host factors and environmental exposures that increase chromosomal damage in stem cells. Damage induced in these cells may persist throughout the reproductive life of the individual. Thus, combining the human-sperm ACM assay (Figure 2) with one of the sperm-FISH assays for aneuploidy (Figure 1) promises a robust approach for detecting paternally transmissible chromosomal damage of both the numerical and the structural type.

Sperm-FISH has several remaining challenges that, while unresolved, will continue to limit its acceptance and utility (Shi and Martin, 2000). These include the following: (1) only a few chromosomes can be investigated within any one assay using visual assessments, (2) the microscope scoring criteria require intensive training and remain subjective, and (3) microscopic scoring is time-consuming limiting the throughput of sperm-FISH analyses. These challenges await the development of automated scoring methods to reduce subjectivity and improve throughput in human as well as rodent sperm-FISH assays (e.g., flow-cytometric analysis or computer-controlled microscopy); and this research is in progress.

Acknowledgments

The authors thank Jack Bishop of NIEHS for his long-standing support and encouragement of rodent sperm-FISH methods. This work was conducted under the auspices of the US DOE by the University of California, LLNL under contract

W-7405-ENG-48 with support from grants NIH/NIEHS ES09117-02 and NIH/NIEHS P42ES04705.

Introductory Review

Imprinting and epigenetic inheritance in human disease

Constantin Polychronakos
McGill University Health Center, Montreal, QC, Canada

1. Introduction

According to the rules of Mendelian inheritance, genetic diseases due to faulty genes located on autosomes (chromosomes other than X or Y) are equally transmitted from the parent of either sex. This is indeed the case for the vast majority of genetic diseases. Why should it matter to the offspring whether a given genetic material comes from the father or the mother? Indeed, once paternal and maternal chromosomes mix upon fertilization, how can the offspring even distinguish which autosomal genes came from which parent?

Actually, in diseases involving the small number of genes subject to the strange phenomenon of parental imprinting, the sex of the transmitting parent does matter. Passing through either the testis or the ovary (the gonads), these genes are "stamped" with an imprint that identifies them as paternal or maternal, respectively. This imprint persists through replication of the DNA as cells derived from the fertilized egg divide to form the entire body and will only be erased and reapplied in the gonads for transmission to the next generation. It usually involves DNA methylation and results in silencing of either the maternal or the paternal copy of the gene involved. Therefore, the level of the protein product of these genes normally corresponds to what comes out of a single gene copy, unlike the case with most other genes, where normal gene dosage corresponds to the product of two copies. Thus, imprinting can be seen as regulating gene dosage, a concept important in understanding its effects on genetic disease.

2. How can imprinting affect disease?

The several ways in which imprinting can play a role in disease can be divided into two broad categories. First, the normal process of imprinting may be disrupted, in which case the offspring has two copies that both behave as if they were maternal, or both as if paternal. This can result in either total lack of expression of the gene (both gene copies silenced) or a double gene dosage (neither copy is silenced). We will see that either of these two situations can result in disease.

Imprinting may also be responsible for disease even when not disrupted. Most genetic diseases are recessive, which means that both copies of the gene involved must be inactivated through mutation for the disease to manifest. If the gene is imprinted, only the single expressed copy need carry the mutation, thus converting what would have been recessive inheritance into dominant. Inheritance does not quite follow the usual autosomal dominant mode, in that (1) the transmitting parent is always the father or always the mother, as the case may be, and (2) the transmitting parent need not be affected, depending on which parent he or she inherited the faulty gene from.

3. The Prader–Willi and Angelman syndromes

The archetypal example of disease due to imprinting is this pair of distinct syndromes each of which can be due to exactly the same mutation, depending on whether it was inherited from, respectively, the father or the mother. In most cases, the mutation is a large DNA deletion on the long arm of chromosome 15 (15q11-13) (Knoll *et al*., 1989). When this deletion is inherited from the father, it results in the Prader–Willi syndrome (PWS). Affected individuals are short, and have symptoms most of which can be attributed to some fault in the development of the central nervous system, specifically the hypothalamus (*see* Article 29, **Imprinting in Prader–Willi and Angelman syndromes**, Volume 1). The most characteristic is an inability to feel satiety after eating, which results in excessive calorie intake and obesity. Their hypothalamus is also unable to stimulate the pituitary gland to make sufficient amounts of gonadotropins, the hormones necessary for pubertal development and sexual function (hypogonadotropic hypogonadism). As newborns, they have markedly decreased muscular tone (floppy babies) that can even be detected by experienced mothers as decreased fetal movements during pregnancy. Some intellectual impairment is common.

Curiously, when inherited from the mother, the exact same chromosome 15 deletion, derived from the same ancestor within an extended family, causes Angelman syndrome (AS) a totally different condition (Knoll *et al*., 1989; Clayton-Smith and Pembrey, 1992). Intellectual impairment in AS is much more severe. Affected individuals have increased muscular tone, jerky, puppet-like movements, a characteristic facial appearance with protruding tongue and bursts of laughter. There is no problem with excessive eating or sexual development (Clayton-Smith and Pembrey, 1992).

About 70% of cases of each syndrome are due to a chromosomal deletion (Knoll *et al*., 1989). The most straightforward explanation is that the deleted region contains (a) gene(s) with exclusive paternal expression, and also gene(s) with exclusive maternal expression, an explanation consistent with the known aggregation of imprinted genes of mixed maternal and paternal expression in the same chromosomal region. Indeed, the *SNRPN*, *IPW*, *Necdin*, and *ZNF127* genes, located in the common PWS/AS region on chr. 15 are paternally expressed, while *UBE3A* shows exclusive maternal expression in the brain. *UBE3A* is almost certainly the gene responsible for AS (Kishino *et al*., 1997), while PWS is more

complex, probably requiring loss of function in more than one of the paternally expressed genes (contiguous-gene syndrome).

The cause of PWS and AS in the 30% of cases with no deletion is a good illustration of the diverse mechanisms by which imprinting can cause disease (Figure 1). Most of such cases of PWS (Nicholls *et al*., 1989) and some of AS (Malcolm *et al*., 1991) have uniparental disomy (UPD) of chr. 15. The term refers to a rare reproductive accident that results in both copies of chr. 15 being derived from the same parent. PWS cases have maternal UPD, designated as $UPD_{mat}[15]$. AS cases, as might be expected, have $UPD_{pat}[15]$. Having two copies of an inactivated gene has the same effect here as a deletion of the sole active copy.

Even more interesting are PWS or AS cases with no deletion and with normal biparental derivation of chr. 15. Methylation analysis of the DNA in such cases shows incorrect imprinting, resulting in both chromosomes behaving as paternal (AS cases) or as maternal (PWS cases) at that locus (Ohta *et al*., 1999). In most cases, the reason is a small DNA deletion that does not affect any of the genes involved but disrupts the imprinting center (IC), a DNA sequence that marks the locus so that the imprinting machinery of the egg or sperm can properly identify it and impart the physical imprint (DNA methylation and, possibly, other less well understood modifications).

Finally, in AS individuals with no evidence of any of the above mechanisms, point mutations in *UBE3A* can cause AS but only if inherited from the mother, thus pinpointing this gene as the one responsible for AS (Kishino *et al*., 1997). No such findings single out one of the paternally expressed genes in PWS, suggesting a contiguous-gene syndrome.

4. Too much of a good thing: transient neonatal diabetes

There is one more imprinting-related, disease-causing mechanism not illustrated in the multiple facets of PWS/AS. Disease can also result from a double dose of a gene. For most genes, dosage need not be regulated precisely. One may have twice as much or half as much of the gene product without consequences (the reason that carriers of recessive disease are healthy). Some genes, however, may cause problems if expressed at higher than normal levels. Such a gene is responsible for transient neonatal diabetes mellitus (TNDM). The pancreas of affected newborns is unable to produce insulin, and death is certain without insulin injections (Temple *et al*., 2000). Characteristically, after a number of weeks or months, the pancreas recovers and normal blood sugars are maintained without treatment. Later in life, a milder form of diabetes may recur that usually does not require insulin treatment (Temple *et al*., 2000).

TNDM may be sporadic or familial. Almost all sporadic cases have $UPD_{pat}[6]$, suggesting either deficiency of a maternally expressed gene on chr. 6 or excess of a paternally expressed one (Temple *et al*., 2000). Not being heritable, UPD cannot explain the familial cases, in which the father is, without exception, the transmitting parent. The mutation inherited from these fathers is a duplication: chr. 6 contains two copies of a small region on its long arm (6q24). This clearly indicates that paternal excess, not maternal deficiency of (an) imprinted gene(s)

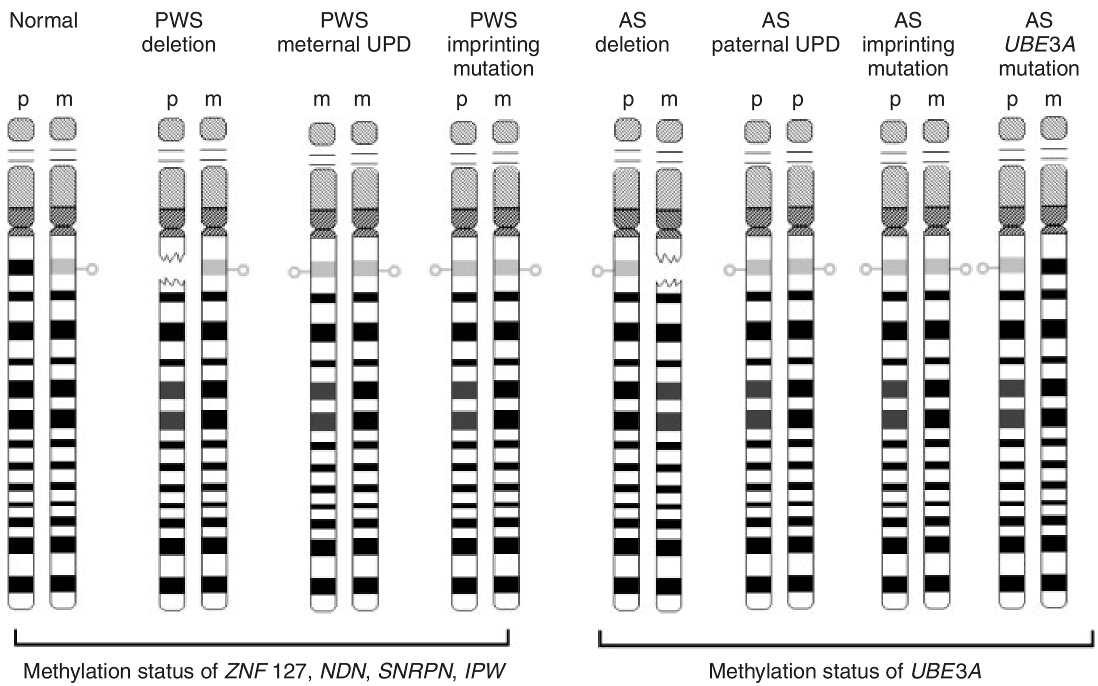

Figure 1 A simple schematic diagram of how parental imprinting is involved in causing Prader–Willi or Angelman syndrome. The various mechanisms, explained in the text, all result in either mutational loss of the only active copy, or the silencing of both, otherwise normal, copies. The light gray area represents the inactivated genes and the attached circle symbolizes DNA methylation

in 6q24 is responsible for TNDM (Temple *et al.*, 2000). Unlike UPD, which usually involves the entire chromosome, duplications are usually quite small. This was used to narrow down the TNDM region to a relatively short interval shared by all the overlapping duplications in different TNDM families (Gardner *et al.*, 2000). Two paternally expressed genes were located in that interval of which the more interesting and better studied is *ZAC*, a DNA-binding protein. *ZAC* is a tumor suppressor (TS), whose role is to prevent uncontrolled cell proliferation. In excess (twice physiologic), it appears to hinder normal proliferation of the insulin-producing β-cells in the developing fetal pancreas, which, for some reason, have a specific sensitivity to this effect.

5. Two other diseases where imprinting plays a role

The Beckwith–Wiedemann syndrome (BWS) is characterized by fetal overgrowth and propensity to embryonal tumors. It is associated with UPD_{pat}[11] and several different chromosomal rearrangements or imprinting defects that essentially make both copies of a region near the tip of the short arm of chr. 11 (11p15.5) behave as if they were paternal. In one subset of BWS cases, the fetal overgrowth is caused by a double dose of the insulin-like growth factor II, a peptide that stimulates fetal growth whose gene (*IGF2*) is normally expressed only from the paternal copy (Giannoukakis *et al.*, 1993). These cases, which also show a gain of DNA methylation in DNA insulator sequences upstream of the nearby and oppositely imprinted *H19* gene, show a high propensity to develop pediatric Wilms tumors. A second, somewhat larger, subset of BWS cases are due to the loss of DNA methylation at another position on chromosome band 11p15.5 (the KvDMR1 imprinting control region), and as a result have reduced expression of a third imprinted gene, *CDKN1C*. These individuals are not highly prone to tumors, but do show severe developmental anomalies, notably abdominal wall defects. This interesting "epigenotype–phenotype correlation" is reviewed in an accompanying article (*see* Article 30, **Beckwith–Wiedemann syndrome**, Volume 1).

Pseudohypoparathyroidism (PHPT Albright's hereditary osteodystrophy) is characterized by resistance to the calcium-regulating parathyroid hormone (PTH) that results in hypocalcemia, despite very high levels of PTH. The defect is on a subunit of a G-protein required for PTH receptor function. Isoforms of the subunit result from transcription of the *GNAS1* gene from alternative promoters, which can be imprinted paternally, maternally, or not at all (*see* Article 31, **Imprinting at the *GNAS* locus and endocrine disease**, Volume 1). Transmission is maternal although the biologically active isoform is not imprinted. We have proposed an explanation for this complex picture in Polychronakos and Kukuvitis (2002), based on the hypothesis that the imprinted isoform is actually a dominant negative inhibitor.

6. Imprinting and cancer

Imprinting may play a role in cancer through silencing of TS genes. Two mutations inactivating both copies of a TS gene in one of the billions of cells in a tissue

gives this one cell a growth advantage that results in a tumor (Knudson'e two-hit hypothesis, *see* Article 65, **Complexity of cancer as a genetic disease**, Volume 2). Often, the second mutation is a large deletion of a chromosomal segment that can be detected as loss of heterozygosity (LOH) at adjacent polymorphic markers. LOH of 11p15.5 (the segment involved in BWS) often occurs in Wilms tumor, a carcinoma of the kidney seen in infants and toddlers, as well as in some other, less common early life cancers that all occur with high frequency in BWS (*see* Article 30, **Beckwith–Wiedemann syndrome**, Volume 1). The deleted segment is always maternal (Schroeder *et al*., 1987), which indicates loss of a maternally expressed TS gene, with imprinting serving as the first "hit". Imprinting of *IGF2* is not universal, as certain tissues of some individuals may express both copies. We first noticed this in white blood cells (Vafiadis *et al*., 1996), and it was subsequently found that this relaxation of imprinting in blood cells correlates with a similar relaxation in the mucosa of the colon (Cui *et al*., 2003). The resulting double dose of the growth stimulator IGF2 may also predispose to colon cancer (Cui *et al*., 2003).

7. Conclusion

Although rare, the diseases caused by imprinting or its disruptions constitute an interesting experiment of nature that has given researchers the opportunity to discover imprinted genes and elucidate some of the mechanisms of this fascinating phenomenon.

Introductory Review

Regulation of DNA methylation by Dnmt3L

Déborah Bourc'his

Timothy H. Bestor

College of Physicians and Surgeons of Columbia University, New York, NY, US

The mammalian genome contains roughly 3×10^7 CpG dinucleotides, and about 60% of these are methylated at the 5-position of the cytosine. Most 5-methycytosine (m^5C) is in transposable elements and their remnants, and removal of methylation by means of mutations in DNA-methyltransferase genes causes the transcriptional activation of transposons in germ and somatic cells. The small fraction of methylation that is not in transposons is involved in the transcriptional repression of certain imprinted genes and in X chromosome inactivation in females. The promoters of tissue-specific genes are not methylated in a pattern that prevents transcription, and the CpG-rich 5′ domains that contain the promoters of 75% of mammalian genes are normally unmethylated at all developmental stages. The common perception of a role for dynamic methylation changes in the regulation of development has not been confirmed, and no gene has been proven to be activated or repressed by reversible DNA methylation. The major biological functions of DNA methylation are transposon repression, monoallelic expression at certain imprinted loci, and X chromosome inactivation in females. Even modest disruption of genomic methylation patterns is lethal to mammals.

Genomic methylation patterns are established and maintained by DNA (cytosine-5) methyltransferases (DNMTs). As shown in Figure 1, mammals have three enzymatically active DNMTs (DNMT1, DNMT3A, and DNMT3B), a tRNA methyltransferase (RNMT2, formerly DNMT2) that is closely related to DNA methyltransferases in sequence and structure, and DNMT3L, a protein that is related to DNMT3A and DNMT3B in framework sequences but which lacks the catalytic motifs that carry out the transmethylation reaction.

Dnmt3A and Dnmt3B are closely related and have low but approximately equivalent enzymatic activities on unmethylated and hemimethylated substrates (Okano *et al*., 1998). Deletion of Dnmt3A does not cause detectable alteration of genomic methylation patterns in somatic cells of homozygous mice, although adult mice lack germ cells and die of a condition similar to aganglionic megacolon (Okano *et al*., 1999). Mice that lack Dnmt3B die as embryos with demethylation

of major satellite DNA but normally methylated euchromatic DNA; the Dnmt3A-Dnmt3B double mutant dies very early with demethylation of all genomic sequences in a manner similar to that of Dnmt1 null mutants (Okano *et al*., 1999). The rare human genetic disorder ICF syndrome (immunodeficiency, centromere instability, and facial anomalies) is due to recessive loss-of-function mutations in the *DNMT3B* gene (Xu *et al*., 1999). Patients with ICF syndrome fail to methylate classical satellite (also known as satellite 2 and 3) sequences on the juxtacentromeric regions of chromosomes 1, 9, and 16; these demethylated chromosomes gain and lose long arms at a very high rate to produce the multiradiate pinwheel chromosomes unique to this disorder (Jeanpierre *et al*., 1993). Dnmt3B is the only mammalian DNA methyltransferase that has been reported to be affected by histone methylation; there is partial demethylation of major satellite DNA (but no reported chromosome destabilization) in mice that lack the heterochromatic histone H3 K9 methyltransferases Suv39h1 and Suv39h2 (Lehnertz *et al*., 2003). DNA methylation abnormalities have not been reported in mouse embryos that lack the euchromatic histone methyltransferase G9a, nor have there been convincing reports of abnormalities of genomic imprinting, X chromosome inactivation, or transposon silencing in mouse embryos that lack specific histone modifying enzymes (reviewed by Goll and Bestor, 2002, 2005). In mammals, all three processes are dependent on DNA methylation.

Dnmt3A and Dnmt3B are clearly required for the establishment of genomic methylation patterns, but neither enzyme has inherent sequence specificity (reviewed by Goll and Bestor, 2005). The outstanding problem in the mammalian DNA methylation field is undoubtedly the source of the sequence specificity for de novo methylation. Recent studies have shown that unidentified regulatory inputs act through Dnmt3L to guide Dnmt3A and Dnmt3B to target sequences, although the initiating signal or signals remain elusive.

1. Dnmt3L: Expression in male and female germ cells

As shown in Figure 2, expression of full-length Dnmt3L is confined to germ cells. The timing of Dnmt3L expression shows striking sexual dimorphism, it is expressed in males only in perinatal prospermatogonia, which will differentiate into spermatogonia and undergo many mitotic divisions before entering meiosis, but in females expression is limited to growing oocytes, which have completed the pachytene stage of Meiosis I.

1.1. *Functions of Dnmt3L in oogenesis*

As shown in Figure 1, Dnmt3L lacks the conserved motifs that mediate transmethylation but is related to Dnmt3A and Dnmt3B in framework regions (Aapola *et al*., 2000). Dnmt3L also fails to methylate DNA in biochemical tests (data not shown). However, Dnmt3L was of special interest because it is the only DNA-methyltransferase homolog whose expression is confined to germ cells at stages at which de novo methylation occurs (Bourc'his *et al*., 2001).

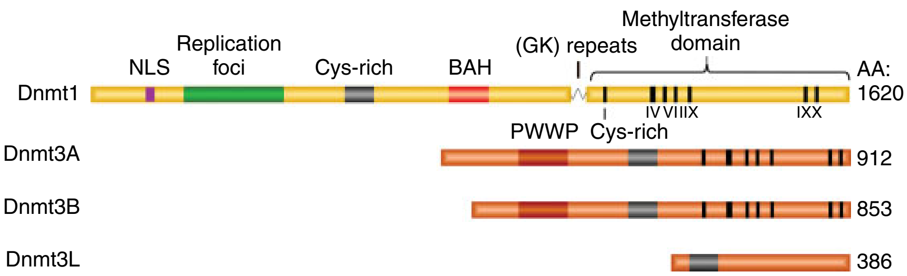

Figure 1 Structure and motif organization of mammalian DNA cytosine methyltransferases. Dnmt3L is expressed specifically in germ cells and is responsible for guiding Dnmt3A and Dnmt3B to target sequences. See Goll and Bestor (2005) for more information

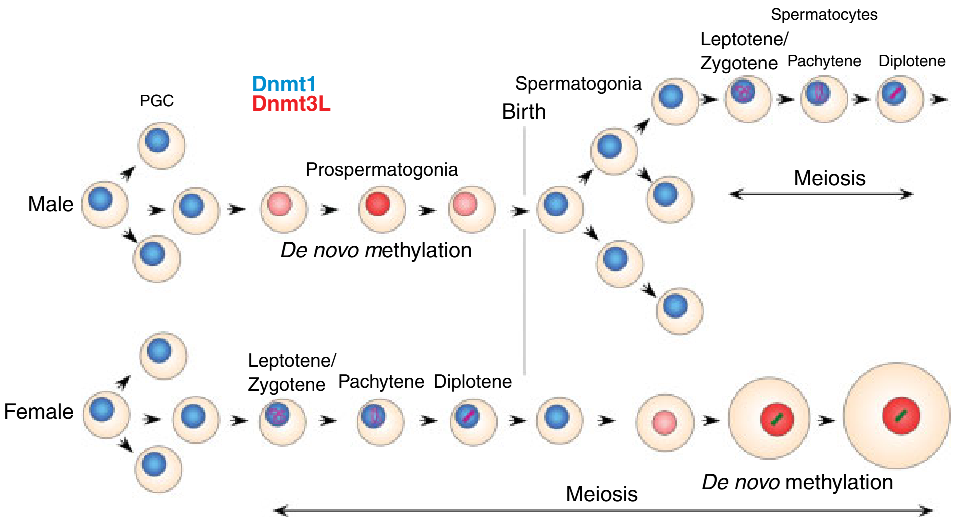

Figure 2 Expression of Dnmt3L and Dnmt1 in male and female germ cells. Intensity of red coloration indicates levels of Dnmt3L, as evaluated by intensity of β-galactosidase expression in animals heterozygous for a β-geo Dnmt3L knock-in allele (Bourc'his *et al*., 2001). Dnmt3L is expressed in premeiotic male germ cells but only in postpachytene (midmeiotic) oocytes in females. Dnmt3L is present only at the stages where genomic imprints are established and, in male germ cells, where transposons undergo de novo DNA methylation

Disruption of the *Dnmt3L* gene by gene targeting in ES cells and insertion of a promoterless β-geo marker into the locus showed that Dnmt3L is expressed in growing oocytes (Bourc'his *et al*., 2001), the stage at which maternal genomic imprints are established (Kono *et al*., 1996). We found that mice homozygous for the disrupted *Dnmt3L* gene were viable and without overt phenotype, although both sexes were sterile. Mutant males were azoospermic, but oogenesis and early development of heterozygous embryos derived from homozygous mutant oocytes was normal; the lethal phenotype was only manifested at e9.5. Such embryos showed signs of nutritional deprivation, and further analysis revealed a failure of chorioallantoic fusion and other dysmorphia of extraembryonic structures (Bourc'his *et al*., 2001). Analysis of expression of imprinted genes showed a

complete loss of imprinting at maternally imprinted loci and a lack of methylation of maternally methylated differentially methylated regions (DMRs). Bisulfite genomic sequencing showed that the imprinting defect was due to a failure to establish genomic imprints in the oocyte, and the normal imprinting of paternally silenced genes in heterozygous offspring of homozygous Dnmt3L-deficient females showed that imprint maintenance in the embryo was normal (Bourc'his *et al*., 2001). This contrasted with the situation in mice that lack Dnmt1o (an oocyte-specific isoform of Dnmt1), when we found that imprint establishment was normal but imprint maintenance in preimplantation embryos was defective (Howell *et al*., 2001). Methylation of sequences other than imprinted regions was normal in heterozygous embryos derived from homozygous *Dnmt3L* mutant oocytes (Bourc'his *et al*., 2001).

1.2. Functions of Dnmt3L in spermatogenesis

In male mice Dnmt3L is expressed at significant levels only in perinatal prospermatogonia, the stage at which paternal genomic imprints are established (Davis *et al*., 1999) and transposons undergo de novo methylation (Walsh *et al*., 1998). Male mice that lack Dnmt3L are outwardly normal except for hypogonadism as adults (Bourc'his *et al*., 2001). The germ cell population is normal at birth, but only the first cohort of germ cells begins meiosis, and none reach the pachytene stage. All mutant meiotic cells show extreme abnormalities of synapsis; grossly abnormal concentrations of synaptonemal complex proteins and nonhomologous synapsis are obvious in nearly all leptotene and zygotene spermatocytes. Adult males are devoid of all germ cells (Bourc'his and Bestor, 2004). This is in striking contrast to Dnmt3L-deficient females, where meiosis and oogenesis are normal and the phenotype is an imprinting defect apparent in heterozygous offspring of homozygous females (Bourc'his *et al*., 2001).

The fact that Dnmt3L-deficient male germ cells show a phenotype only after the stage at which Dnmt3L protein is no longer expressed suggests an epigenetic or gene silencing defect. Homozygous mutant male germ cells were purified and found to suffer global demethylation of the euchromatic genome (Bourc'his and Bestor, 2004).

Transposons contain the large majority of m^5C present in the mammalian genome (Yoder *et al*., 1997), and demethylation of the major transposon classes (IAP elements and LINE-1 elements) was observed in Dnmt3L-deficient male germ cells. However, there was little or no demethylation of major or minor satellite DNA when compared with controls. This indicates that the methylation of heterochromatic satellite DNA is controlled by mechanisms distinct from those that control the methylation of euchromatic sequences. Other data support this conclusion; mutations in the *DNMT3B* gene in humans cause demethylation only of classical satellite (which is analogous to mouse major satellite) in ICF syndrome patients (Jeanpierre *et al*., 1993; Xu *et al*., 1999), and the methylation status of major satellite (but not of other sequences) is affected in mice by loss of the histone methyltransferases Suv39h1 and Suv39h2 (Lehnertz *et al*., 2003), although the magnitude of the effect is much smaller.

The host defense hypothesis predicts that demethylation of transposons in germ cells will cause their transcriptional activation (Bestor, 1990; Yoder *et al*., 1997; Bestor, 2003). Deprivation of Dnmt3L causes mass reanimation of LINE-1 and IAP transcripts observed by blot hybridization and in situ hybridization (Bourc'his and Bestor, 2004). *Dnmt3L* is therefore the first gene shown to be required for the silencing of transposons in germ cells of any organism. It is notable that homozygous loss-of-function mutations in Dnmt1 cause reactivation of IAP transcription in somatic cells (Walsh *et al*., 1998), but LINE-1 elements are not reactivated (Bourc'his and Bestor, 2004); this is likely to reflect the germ cell-specific nature of the promoter in LINE-1 elements (Ostertag *et al*., 2002). LINE-1 elements are thought to be the source of reverse transcriptase for all retroposons, and the coexpression of IAP elements and LINE-1 elements suggests that active transposition of multiple retroposon classes will occur in Dnmt3L-deficient prospermatogonia and spermatogonia.

Dnmt3L is evolving rapidly by comparison to other mammalian DNA-methyltransferase orthologs (Bestor and Bourc'his, 2004). Rapid evolution often reflects an evolutionary chase in which a parasite evolves at a high rate to escape host defense systems, which are then brought under selective pressures for rapid evolution to counter the innovation of the parasite. Transposons represent the most rapidly diverging sequences within host genomes as a result of incessant selective pressures to evade host defense mechanisms. The rate of evolution of DNA methyltransferases is constrained by the requirement to preserve enzymatic activity. This constraint will limit the diversification of these enzymes and favor the evolution of adapter proteins free of this constraint and therefore capable of evolution at a much greater rate. It is suggested that Dnmt3L arose from an enzymatically active Dnmt3 family member in this way, and that the protein now has a regulatory function and cooperates with other proteins in the recognition and de novo methylation of transposons (in male germ cells) and imprinted genes in both germlines.

2. Conclusion

While recent progress has been significant, a number of outstanding questions remain with respect to the biological function of Dnmt3L and the regulation of de novo methylation in germ cells. Why is Dnmt3L required for the methylation of dispersed repeats and largely dispensable for methylation at DMRs in male germ cells, and why is it dispensable for methylation of dispersed repeats but essential for the methylation of single-copy sequences associated with imprinted genes in female germ cells? What signal does Dnmt3L interpret before recruiting Dnmt3A and Dnmt3B; is it recognition of atypical DNA structures such as cruciforms or homology–heterology boundaries in strand-exchange intermediates? Is it particular patterns of histone modifications, or combinations of proteins of the Polycomb and trithorax groups? Are there pathways that regulate DNA methylation in a manner that is independent of Dnmt3L? The identification of Dnmt3L as a regulator of de novo methylation provides an opportunity to discover interacting factors and to

finally identify the cues that designate specific regions of the genome for de novo methylation in germ cells.

The histone code and epigenetic inheritance

Andrew R. Hoffman and Thanh H. Vu
Stanford University School of Medicine, Palo Alto, CA, USA

1. Histones and chromatin

Histones constitute a family of remarkably conserved proteins that are assembled into nucleosomes that are composed of eight core proteins arrayed as four heterodimers of canonical histones (H2A:H2B, H3:H4, H3:H4, H2A:H2B) around which 147 bp of DNA is wrapped 1.7 times (Luger *et al*., 1997). The nucleosomes, which are connected to each other by 20–60 bp of linker DNA, can then be compacted into a 30-nm fiber to form a more closed and silenced structure (Horn and Peterson, 2002). In conjunction with other proteins involved with DNA replication and packaging, the nucleosomes and DNA are referred to as chromatin. The DNA that is wound about the nucleosome is partially blocked, and only the portion of the DNA that faces away from the histones or is a part of the linker DNA has ready access to DNA polymerases, and regulatory proteins and complexes. Thus, while the histones serve to compact the DNA into the small nuclear space, biochemical machinery must exist to allow DNA to dissociate from the nucleosome on a temporary basis to allow for contact with DNA-modifying protein or RNA complexes and to permit DNA replication and gene transcription. Much of this work may be achieved through nucleosome remodeling complexes, which expose DNA to potential protein binders and partners. By hydrolyzing ATP to provide the energy needed to weaken the DNA:nucleosome interaction and to provide torsion on the DNA helix, DNA loops are opened, and bulges appear, thereby allowing the nucleosomes to slide over the DNA strand. Covalent modifications of the histone octamer represent another mechanism that can alter nucleosome:DNA interactions.

2. The histone code

Histones are substrates for an enormous number of posttranslational enzymatic modifications, including acetylation, methylation, phosphorylation, ubiquitination, and ADP-ribosylation on specific amino acid residues. These modifications occur

in a regulated and nonrandom manner, and the discovery that certain modifications are associated with changes in DNA transcription led to the hypothesis that these modified amino acid residues constituted a distinct "histone code" that regulates gene expression (Turner, 2000; Jenuwein and Allis, 2001). The presence of a code stipulates that each histone molecule possesses a linear array of modifiable amino acid residues and that these modifications enhance biologically productive interactions with chromatin-associated and other nuclear proteins. Higher-order chromatin structure is dependent on the operational sum of these modifications, and the code could be combinatorial. The code is read by nonhistone proteins whose binding to chromatin is determined by specific histone modifications, and the code is deciphered by viewing it as a series of independent modifications arrayed in a linear sequence, or as explicit combinations of modified amino acids. Moreover, the presence of one modification may stimulate further histone modifications on the same (in cis) or on adjoining histones (in trans).

The abundant evidence that acetylated histones were associated with open chromatin, and increased gene transcription was the first suggestion that histone modifications are a molecular signal (Grunstein, 1997). Acetylation of histone 3, lysine 9 (H3K9) was associated with gene expression. The demonstration that histone methylation could lead to gene silencing when it was on H3K9 and to gene expression when histone 3, lysine 4 (H3K4) was methylated demonstrated that the specificity of the code was determined by the particular amino acid residue in conjunction with the precise chemical modification (Noma *et al*., 2001). This detailed specificity was further delineated when it was shown that trimethylation, but not mono- or dimethylation, of H3K4 coded for gene activation (Santos-Rosa *et al*., 2002).

Most histone modifications have been described on the histone tail, where the enzymatic machinery has relatively free access to the relevant amino acid substrates. These modified histones then become adhesive, receptor-like molecules that can attract, recruit, and bind extremely specific protein complexes that can modulate transcription. Acetylated lysines on histone H3 bind a series of proteins containing a bromodomain motif, leading to an increase in gene expression, while H3K9 methylation attracts chromodomain-containing proteins and HP1 (Jenuwein and Allis, 2001), leading to the formation of heterochromatin and gene silencing.

In addition to modifications on the histone tail, the core portion of histones can also undergo posttranslational additions. These core modifications, which regulate nucleosome mobility, can also be governed by the histone code (Cosgrove *et al*., 2004). Since much of the core is associated with tightly wound DNA, it is likely that remodeling complexes must first weaken DNA:nucleosome interactions in order to expose the amino acid substrates to the acetylating, phosphorylating, or methylating enzymes. While the functions of core modifications are less clearly understood, it is clear that their histone code may play a vital transcriptional role, as a stable remodeled state can be generated even with tailless nucleosomes. Covalent histone modifications can also lead to an altered electrochemical "charge patch" that could theoretically modulate histone structure or its binding to DNA independent of any histone signal decoding.

3. Combinatorial code

It is likely that the consequence of any specific histone modification depends upon the modifications of its neighbors. The histone code is combinatorial in that multiple modifications may reside on a single histone molecule, and the set of modifications may be read together as an intelligible message. For example, one modification may lead to the recruitment of enzymatic complexes that promote other nearby histone modifications. In some systems, the combination of acetylated histone 3, lysine 9 (H3K9-Ac) and phosphorylated histone 3, serine 10 (H3 S10-P) synergize to stimulate gene expression, and, conversely, methylated histone 3, lysine 9 (H3K9-Me) may inhibit the establishment of H3 S10-P. In an elegant explication of the control IFN-beta, it was shown that three specific lysine acetylation reactions (H4K8, H3K9, and H3K14) at the promoter region were necessary to recruit two specific bromodomain-containing transcription factors and stimulate gene expression (Agalioti *et al*., 2002). Schreiber and Bernstein have proposed a creative dynamic model of chromatin, comparing the histone code to cellular signaling networks. As in the case with signal transducing receptors, posttranslational modifications of histones leads to the creation of docking sites that can recruit regulatory proteins in high concentrations. In both systems, multiple modifications, occurring in varying regions and in varying chronological sequences, lead to feedback loops, which can provide stability, adaptability, and robustness, thereby promoting an array of consequences under exquisitely ordered control (Schreiber and Bernstein, 2002).

The task of interpreting the histone code is still in its early stages, as it is not yet clear how we have identified the full gamut of covalent modifications and attachments, or how the various combinations of such changes (e.g., H4 acetylation and H3 K9 methylation) on a single nucleosome or on adjacent nucleosomes interact with one another to modify gene expression (Spotswood and Turner, 2002). While histone acetylation and phosphorylation are rapidly reversible modifications, histone methylation at first appeared to be a permanent mark, as no direct demethylases had been discovered. This situation changed very recently, however, with the discovery of an enzyme that can specifically demethylate the stimulatory modification, dimethyl-lysine 4 in histone H3 (Shi *et al*., 2004). Direct enzymatic demethylation of the inhibitory H3 K9 methyl modification has not yet been demonstrated. Moreover, indirect demethylation of CpG can occur through methylcytosine deamination, which leads to a C-T transitional mutation, in conjunction with T:G mismatch repair (Morgan *et al*., 2004), and methylarginine in histone proteins can be converted to citrulline by deimination (Cuthbert *et al*., 2004).

4. Epigenetic code

Epigenetics refers to a mechanism whereby genetic information is heritably passed to the next generation of daughter cells without altering the DNA sequence. Methylation of CpG nucleotides in CpG islands in DNA is generally associated with silencing of gene transcription, and this methylation pattern is passed down to daughter cells after mitosis. Thus, this form of epigenetic gene silencing may play

an important role in cellular differentiation, allowing cells to express a restricted repertoire of genes. Histone modifications as well as DNA methylation, moreover, have the unique ability to be encoded and maintained through cell division as epigenetic memory. The interactions between histone modifications and DNA methylation in the regulation of genomic imprinting and the related phenomenon of X-inactivation have been intensively investigated. For example, methylation of H3K4 is seen on the active X chromosome, while H3K9 methylation is associated with the inactive X chromosome (Boggs *et al*., 2002). In *Saccharomyces*, H3 methylation is dependent upon prior ubiquitination of histone 2B (Dover *et al*., 2002). DNA methylation of *Snrpn* is related to histone H3 and not H4 deacetylation (Gregory *et al*., 2001), while simultaneous H3 and H4 acetylation is associated with transcription of *Igf2/H19* (Grandjean *et al*., 2001). Using compounds such as butyrate and trichostatin A, which act as histone deacetylase inhibitors, we have shown that changing the state of histone acetylation can result in de novo expression of the imprinted allele. Moreover, the enhanced histone acetylation induced by these drugs also leads to decreases in DNA methylation, but drugs that inhibit histone deacetylases (HDACs) often do not restore full expression of previously silenced genes, as some DNA methylation will not be affected by changes in histone acetylation (Hu *et al*., 1998).

DNA methyltransferases (DNMTs) and HDACs can interact in complex and intricate ways to alter chromatin structure (Li, 2002). The primacy of the histone code versus DNA methylation in the establishment of the epigenetic state has been extensively studied. Thus, DNMT1 binds HDACs (Fuks *et al*., 2000), and the process of DNA methylation can lead directly to histone deacetylation, or vice versa. Moreover, a number of methyl-CpG-binding proteins become associated with HDAC-protein complexes, further integrating DNA methylation with changes in histone structure (Jones *et al*., 1998). De novo CpG methylation normally occurs *after* chromatin changes have rendered a gene transcriptionally silenced, suggesting that the major function of DNA methylation is to affect the stable silencing of a gene. Using an ingenious transgenic approach, Cedar's lab demonstrated that DNA methylation induces the deacetylation of H4 and the methylation of H3K9, and inhibits the methylation of H3K4. They conclude that DNA methylation is sufficient to induce a closed chromatin structure (Hashimshony *et al*., 2003). In *Neurospora*, DNA methylation occurs only after histone H3K9 methylation has been achieved (Tamaru and Selker, 2001). It is our view that the minute-by-minute transcriptional regulation of a gene is determined by the rapid and reversible on/off modifications to histone molecules (Spotswood and Turner, 2002), primarily acetylation and phosphorylation reactions. Long-term silencing, on the other hand, is initiated by histone methylation (e.g., H3K9 or H3K27) and is firmly cemented by the relatively irreversible methylation of CpG dinucleotides. In this paradigm, epigenetic regulation stems from dynamic histone modifications, leading to changes in DNA methylation. In the absence of DNA methylation (DNA methyltransferase-I [*Dnmt1*] deficient mice), imprinting is severely disrupted, indicating that histone modifications alone are not sufficient for persistent monoallelic expression (Howell *et al*., 2001).

5. How is the epigenetic code transmitted to daughter cells?

The mechanism for the transmission of DNA methylation after mitosis appears to be straightforward. After the DNA is replicated, one strand of the double helix will contain the original DNA (which is methylated), while the other strand of newly synthesized DNA will contain unmethylated DNA. This hemi-methylated DNA is the preferred substrate for DNMT1, which then transfers methyl groups to all of the hemi-methylated symmetric CpGs in the DNA daughter strand (Bestor, 1992). Replicating the histone code after mitosis is more complicated, however, because the myriad of modifications are regulated by a large array of enzymes and remodeling complexes. After DNA replication, the various sets of modified histones are distributed in a random semiconservative pattern to the newly formed nucleosomes where they are matched with newly synthesized (and presumably unmodified) histones, so that, on average, each set of the histone modifications are present in a density 50% of that seen in the original nucleosome. It has been suggested that chromatin assembly factor (CAF)-I is recruited by proliferating cell nuclear antigen as the DNA is being replicated. CAF1 binds to HP1, which then recruits a set of enzymes, including DNMT1, histone deacetylases, and histone methyltransferases, which can theoretically replicate the histone code (Maison and Almouzni, 2004). However, it is not at all clear how the very specific combination of modifications can be duplicated, since it is not apparent what template the enzymes could utilize. It has been argued that modifications such as H3K9-Me can recruit a H3K9-methyltransferase that can duplicate the modification (or lead to spreading of the modification in cis) (Maison and Almouzni, 2004), and acetylated lysines can recruit bromodomain proteins in complexes that may contain histone acetyltransferase (HAT) activity, but self-duplicating machinery has not been demonstrated for all of the modifications. Therefore, it has been suggested that in some cases, duplication of the code does not occur during replication, but during gene transcription when the nucleosome:DNA interaction is weakened. This would result in two complementary processes for heritable transmission of the code, one that is replication-dependent (RD) and one that is transcription-dependent (TD) (Henikoff *et al*., 2004). The RD method would replicate the histone code via chromodomain-containing proteins, and the TD would operate through proteins with bromodomains. The transcription-coupled nucleosome replacement theory suggests that active nucleosomes are replaced by ATP-dependent remodeling complexes that deposit newly synthesized histones containing the variant histone H3.3, which may alter the interactions of the nucleosome with DNA. H3.3 is deposited during all phases of the cell cycle except S-phase, and it has been shown to replace H3 containing H3K9Me after the induction of transcription. This theory suggests that the *variant* histones, more than a histone code dependent upon posttranslational modifications, determine the transcriptional valence of the chromatin, and the theory also suggests that the histones of all actively transcribed genes will be replaced during one-cell generation. Data to confirm or reject this theory awaits the availability of specific antibodies to variant histones, but it is our view that only H3 histones containing silencing modifications (K9-Me and K27-Me) may be replaced by H3.3 and the activating modifications remain in place. Thus, it is likely that some but not all of the nucleosomes

are replaced. Transcriptionally active chromatin normally harbors no or very low levels of H3K9-Me and H3K27-Me. The procession of transcription may help to "clean out" some of the sporadic silent code (H3K9-Me, H3K27-Me) along the transcriptional passage. It has been shown that read-through transcription can activate repressed chromatin domains marked by H3K27-Me and the Polycomb complex in Drosophila bithorax (Bender and Fitzgerald, 2002). However, as we have noticed in a number of imprinted genes, such as *Gnas*, which contain overlapping sense and antisense transcripts, on each parental chromosome, read -through transcription in a repressed promoter region fails to switch the promoter from a repressed state to an active one (Li *et al*., 2004). On each parental chromosome, the repressed promoters are strictly maintained by histone H3K9 methylation and by DNA methylation. DNA methylation is generally absent in Drosophila, a fact that might partly explain the observed switching from a silenced to an active state by read-through transcription in the fly. It is likely that epigenetic inheritance and maintenance in mammals, at least in imprinted genes, is more strictly governed by both histone methylation and DNA methylation, and that repressed chromatin domains cannot be reversed to an active state by read-through transcription.

6. Epigenetic inheritance and genomic imprinting

While most autosomal genes are expressed in an equivalent manner from both parental alleles, a small number of important genes are expressed only from one specific parental allele. These genes, which are often important in growth, development, and behavior, are said to be imprinted, and enormous interest has been aroused in solving the puzzle of how a cell can discern the parental origin of an allele and how the transcriptional machinery is able to operate on only one of the two alleles. A number of imprinted genes contain reciprocally imprinted antisense transcripts that originate within the gene and are transcribed from the parental allele opposite of that of the sense allele.

7. Epigenetic domains and the fine print of the histone code of *Gnas*

In the formation of heterochromatin, gene silencing enforced by H3K9 methylation leads to the formation of binding sites for proteins like Swi6 (in yeast), which then recruits histone methyltransferases, leading to the spreading of H3K9 Me and further silencing of adjacent nucleosomes. This spreading can be diffused, or it may be interrupted. Ultimately, this progression is blocked by insulators that prevent this repressive spread and allows for the subsequent development of histone modifications that promote gene expression. In some circumstances, a single nucleosome with a specific modification can control gene expression: one nucleosome containing H3K9 inhibits *RB* expression (Nielsen *et al*., 2001). In yet other systems, stimulatory and inhibitory regions of the genome lie side by side,

and the histone code should be able to provide the epigenetic message to regulate gene expression.

In the *Gnas* gene, there are various imprinted transcripts that arise within several thousand bases of one another. On the maternal chromosome, the *Nesp* transcript is transcribed through three silenced domains corresponding to the Nesp antisense (*Nespas*), *Xlαs*, and Exon 1A; conversely, on the paternal allele, the active *Nespas* is transcribed through the silenced *Nesp* region. Since the region between *Nesp* and *Xlαs* is relatively small (∼10 kb) and since the change from active to suppressed regions must involve epigenetically determined boundaries, we studied the sequential changes in the histone code in nucleosomes spanning this gene (Li *et al*., 2004). Surprisingly, the various activating and silencing signals segregated independently on nucleosomes over this area. We found that there were two allelic switch regions (ASR) that marked separate boundaries of epigenetic signaling in the region between the reciprocally imprinted *Nesp* and *Nespas* promoters. ASR1 has a terminal boundary just downstream of *Nesp*, and it is characterized by an activating region that is rich in histone acetylation and H3K4 methylation. Further downstream, the nucleosomes assume another configuration (ASR2), which is characterized by silencing epigenetic changes (H3K9Me and DNA methylation). A relative boundary element may exist at this interface between the two ASRs, although it is possible that there exist nucleosomes that harbor both activating as well as silencing signals. It seems likely that there are two independent regulatory mechanisms at play, one governing the activating modifications and the one silencing changes. The variety of modifications seen throughout the *Gnas* chromatin raises the question of where the histone code is read. Does the epigenetic transcriptional machinery operate only at promoter regions or is there an important histone code that resides over most of the gene or even the entire imprinted domain?

8. Histone code overrides the DNA imprint

The relative roles of DNA methylation and the histone code in the regulation of genomic imprinting has been a topic of great interest. While many studies have suggested that DNA methylation is the primordial imprint that determines allelic expression throughout development, several recent studies have shown that the histone modifications can override DNA methylation in the expression of imprinted genes. The imprinting of the mouse *Igf2r* gene in peripheral issues is regulated through a differentially methylated DNA region in the first intron and by the presence of a nontranslated RNA antisense, *Air* (Sleutels *et al*., 2002). In the central nervous system, however, *Igf2r* is biallelically expressed, even though *Air* is expressed (Hu *et al*., 1999). In human *IGF2R*, expression is always biallelic; even though the intronic DMR (differentially methylated region) is present in the human gene, no antisense RNA is transcribed (Vu *et al*., 2004). This discrepancy was difficult to reconcile with a general antisense model of imprinting until it was shown that the tissue-specific and species-specific imprinting status of *Igf2r* could be predicted by examining the histone code, rather than the DNA methylation or RNA antisense (Vu *et al*., 2004). In all cases, allele-specific expression is

determined by the presence of H3K4-Me (stimulatory) or H3K9-Me (inhibitory) at the promoter region.

Another example of the dominance of the histone code over DNA methylation in determining gene expression is found in the regulation of a cluster of genes on mouse chromosome 7. The imprinting center 2 (IC2) on mouse chromosome 7 controls the regulation of several imprinted genes, where one germ-line DMR and two somatically acquired DMRs have been recognized in this cluster. Imprinting in embryonic stem (ES) cells and in extraembryonic tissues (placenta) extends beyond the imprinting domain in embryos to ∼700-kb region flanking the IC2. The imprinting of these distal imprinted genes, in contrast to the proximal genes, does not depend upon DNA methylation, as the distal genes remain imprinted in the *Dnmt1* -/- placenta. The imprinting of both distal and proximal genes, however, is consistent with the association of H3K9Me and H3K27Me methylation in the silenced allele, and H3KAc and H3K4Me in the expressed allele. Allele-specific histone modifications and imprinting are disrupted by IC2 deletion (Lewis *et al*., 2004). Feil, Reik, and colleagues proposed that the histone code is the primordial regulator of imprinting, and remains the major factor allowing specific allelic expression in ES cells and in the placenta. In later development, in differentiated ES cells and in embryos, stable imprinting requires the recruitment of DNA methylation to make the imprinting permanent.

9. Conclusion

The multitude of posttranslational histone modifications constitute a code that can be read by the cell's transcriptional machinery to alter gene expression. Numerous questions concerning the histone code remain to be answered however. In particular, the precise mechanisms underlying the heritability of the various amino acid modifications are yet to be convincingly elucidated. Are there developmental-specific or tissue-specific aspects to the code? Is the code read the same way for all genes? Where do we look for the code: should we concentrate on nucleosomes associated with the promoter regions of the gene only, or must we examine all of the nucleosomes associated with a gene to understand how the histone code regulates gene expression?

Imprinting and epigenetics in mouse models and embryogenesis: understanding the requirement for both parental genomes

Mellissa R. W. Mann
The University of Western Ontario, London, ON, Canada

1. Introduction

Twenty years ago, the developmental fate of uniparental embryos was described in mammals. Elegant nuclear transplantation studies in the mouse determined that both a maternal and a paternal genome are required to complete normal development (McGrath and Solter, 1984; Barton *et al*., 1984). Parthenogenetic and gynogenetic embryos possess only maternally derived chromosomes. The most advanced of these embryos fail to proceed beyond the early limb-bud stage. Extraembryonic tissues are poorly developed. Conversely, androgenetic embryos possess only paternally derived genomes. These embryos rarely advance to the unturned, head-fold stage, and the embryo proper shows poor development. These phenotypes suggest that genes required for embryonic development are expressed from the maternal genome, while genes required for extraembryonic development are transcribed from the paternal genome.

Further analysis indicates that this is a somewhat simplified view. Examination of uniparental embryos and aggregation chimeras revealed phenotypic abnormalities in both embryonic and extraembryonic lineages (Tables 1 and 2). Developmental differences possibly lie in the ability of uniparental cells to proliferate and differentiate. Parthenotes are characterized by a failure to maintain undifferentiated stem cell populations; terminally differentiated cells are overabundant (Sturm *et al*., 1994; Newman-Smith and Werb, 1995). Androgenetic chimeras display an increased rate of cell proliferation (Fundele *et al*., 1995). Thus, the original observation of an antipodal effect of androgenetic and parthenogenetic cells on growth and development is supported.

Noncomplementation of parental genomes indicates that transcriptional regulation of specific genes is dependent on germline origin. Two epigenetic phenomena direct monoallelic expression based on parental origin in the mouse, imprinted X chromosome inactivation (XCI), and genomic imprinting.

Table 1 Phenotypic characteristics of uniparental embryos

Parthenogenetic embryos	Androgenetic embryos
Growth retarded	Early embryonic growth retardation
Few proliferating cells	Trophoblast hyperplasia
Overabundant terminally differentiated cells	Hyperproliferation trophoblast giant cells
Degeneration of polar trophectoderm	Hyperproliferation chorion
Reduced endoreduplication in giant cells	Poor infiltration of chorion by allantois
Lack ectoplacental cone and extraembryonic ectoderm	Poor infiltration chorionic ectoderm into giant cell layer
Thickened extracellular matrix	Distension of pericardial cavity
Chorio-allantoic failure	Weight increase
Enlarged or bulbous allantois	Increased somite number
Poor yolk sac vasculature	Increase in anterior–posterior length
Mesoderm absent/disorganized	
Neural tube defects	
Abnormal, small somites	
Reduced somite number	
Thinner myocardial layer in heart	

Sturm *et al*. (1994) and Obata *et al*. (2000).

Table 2 Phenotypic characteristics of uniparental cells in aggregation chimeras

Parthenogenetic chimeras	Androgenetic chimeras
Growth retarded	Weight/size increase
Poor yolk sac vasculature	Increase in anterior–posterior length
Chorio-allantoic failure	Craniofacial abnormalities
Swollen or bulbous allantois	Sternum shortened/compressed
Defective labyrinthine development	Vertebrae shortened/thickened
Stunted/reduced somite number	Scoliosis
Thinner myocardial layer in heart	Rib cartilage hyperplasia
	Hypo-ossification ribs and skull
	Enlarged, distorted, and fused ribs
	Shortened limbs
	Enlarged and/or fused digits
	Postaxial polydactyly
	Enlarged and disorganized heart
	Umbilical hernia
	Abdominal swelling/liver enlargement
	Abdominal muscle wall defects
	Lack mature brown fat
	Eyelid fusion failure

2. Imprinted XCI in extraembryonic development

Dosage compensation of X-linked genes is accomplished by inactivation of one X chromosome in female mammals (*see* Article 40, **Spreading of X-chromosome inactivation**, Volume 1 and Article 41, **Initiation of X-chromosome inactivation**, Volume 1). In rodents, extraembryonic tissues undergo preferential inactivation of

the paternal X chromosome (X^P). X-inactivation is regulated in cis by the *Xist* noncoding RNA and its antisense transcript, *Tsix* (Verona *et al*., 2003; Takagi, 2003). *Xist* is transcribed from the paternal X chromosome during preimplantation development and associates with the X chromosome that is to be inactivated, while *Tsix* is transcribed from the maternal X (X^M).

As parthenogenetic embryos possess only maternally derived chromosomes, developmental abnormalities could result from aberrant X-linked gene dosage. In fact, parthenotes fail to undergo XCI; both maternal X chromosomes repress *Xist* and remain active (Figure 1) (Takagi, 2003). If the phenotype associated with parthenogenesis is due only to the inability to inactivate a second maternal X chromosome, then X^MO parthenotes should not suffer the same fate, as X chromosome dosage should be normal. X^MO parthenogenetic embryos display the same compromised development as X^MX^M parthenotes (Mann and Lovell-Badge, 1987), indicating that developmental defects cannot be attributed solely to excessive X-linked gene expression; lack of paternally transcribed, imprinted genes must also contribute to parthenote degeneration.

Conversely, if parthenogenetic failure is due solely to a supernumerary maternal X, embryos with maternal X disomy should be equivalent to parthenotes. $X^MX^MX^P$ and X^MX^MY embryos repress *Xist* and possess two active X chromosomes (Figure 1) (Takagi, 2003). Phenotypically, they bear a striking resemblance to parthenotes. Aggregation of maternal X disomic embryos with tetraploid embryos, which contribute functional trophectoderm, rescues this phenotype. Thus, the

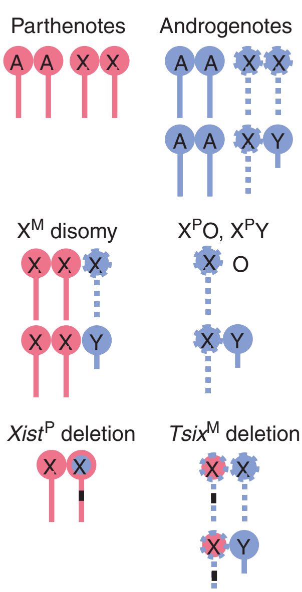

Figure 1 Imprinted XCI in various mouse embryos. Red and blue are maternal (M) and paternal (P) chromosomes, respectively (autosomes: A, X chromosome: X). Solid lines are active and dashed lines are inactive Xs. Black bar indicates deletion

inability to inactivate an extra maternal X chromosome contributes to early lethality of parthenogenetic embryos by impairing extraembryonic development.

Fatality induced by two active X chromosomes was unequivocally demonstrated by engineering mice with a paternally inherited *Xist* deletion. Loss of *Xist* expression results in the paternal X chromosome adopting a maternal epigenotype (Marahrens *et al*., 1997). Thus, neither the maternal nor the paternal X chromosome is inactivated (Figure 1). Mutant embryos display a remarkably similar phenotype to parthenotes. Mice that are $X^{P}O$ and carry the *Xist* deletion are normal, demonstrating that it is a second active X chromosome that is responsible for defective trophoblast development.

Similar to parthenotes, aberrant X-linked gene expression may factor into the developmental fate of androgenetic embryos. During preimplantation, androgenotes display ectopic *Xist* localization from all X^{P} chromosomes, indicative of imprinted XCI (Figure 1) (Takagi, 2003). If the phenotype of androgenetic embryos is due solely to functional nullisomy for the X chromosome, then $X^{P}O$ and $X^{P}Y$ embryos should display similar developmental sequelae to androgenotes. These embryos exhibit decreased trophoblast differentiation, developmental delay, and a small ectoplacental cone (Jamieson *et al*., 1998); their less severe phenotype indicates that lack of expression from maternally transcribed, imprinted genes contributes to androgenetic demise. Reactivation of genes distally located from the X-inactivation center or the X chromosome itself may also ameliorate the phenotype.

One possible explanation for ectopic *Xist* expression is loss of *Tsix* expression. Maternal deletion of *Tsix* leads to derepression of the silent, maternal *Xist* allele (Lee, 2000; Sado *et al*., 2001), and the maternal X chromosome takes on a paternal epigenotype (Figure 1). *Tsix* mutants are characterized by severe embryonic losses and display features common to androgenetic embryos. Early postimplantation, *Tsix* mutants are developmentally retarded. The ectoplacental cone fails to expand into decidua, and allantois and chorion are disorganized (Sado *et al*., 2001). One significant difference between androgenotes and *Tsix* deficient mice is that a small percentage of the latter survive, albeit with growth retardation (Lee, 2000; Sado *et al*., 2001), indicating that aberrant XCI is not the only determinant in defective extraembryonic development and androgenetic lethality. In summary, extraembryonic tissues are susceptible to perturbation in X chromosome dosage. However, imprinted XCI alone cannot account for the noncomplementarity of the parental genomes in placental development; genomic imprinting must also play a role.

3. Genomic imprinting during embryogenesis

Genomic imprinting is an epigenetic transcriptional regulatory mechanism that is established in the parental gametes and is manifested as parental-restricted expression in developing offspring (Verona *et al*., 2003). Biological functions for imprinted genes come from studies involving mice with uniparental disomy/duplications, and with specific gene deficiencies. Uniparental duplication is a condition in which an individual inherits two copies of a chromosomal region from one parent and no copy from the other parent. An imprinted phenotype may result from overexpression and/or loss of expression of genes that exhibit

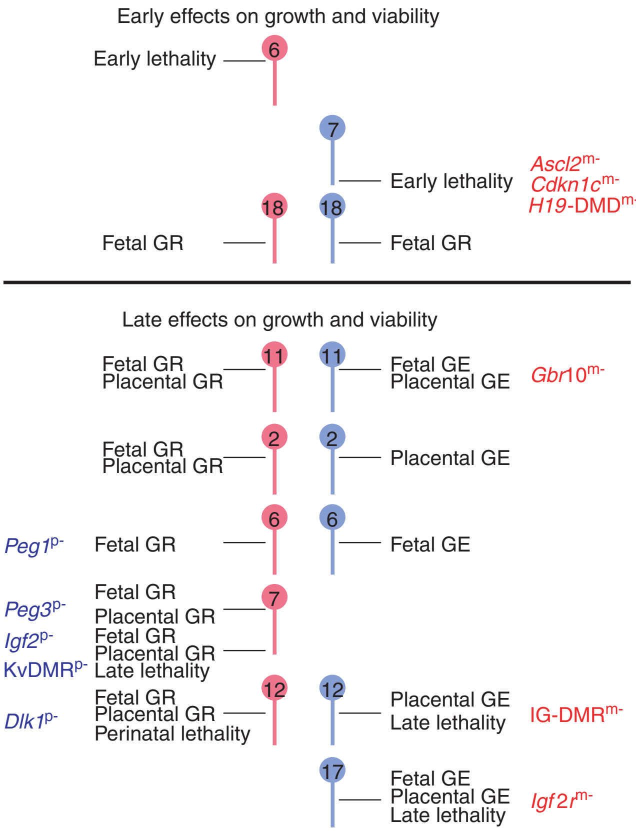

Figure 2 Effects of uniparental duplications on fetal and placental development. Only chromosomal region with imprinting effects on embryogenesis are shown (Beechey *et al*., 2003). Maternal chromosomes/genes are in red, while paternal chromosomes/genes are in blue. GR: growth retardation, GE: growth enhancement. Imprinted genes and imprinting control regions contributing to growth and viability, as determined by targeted mutation, are indicated (m- maternal deletion, p- paternal deletion) (Reproduced by permission of MRC Mammalian Genetics Unit, Harwell, Oxfordshire, Imprinting. Website **http://www.mgu.har.ac.uk/research/imprinting**)

parental-origin-dependent transcription. Several chromosomal regions affect embryonic development and viability when present from only one parent (Figure 2) (Beechey *et al*., 2003). Note that fetal and placental growth effects may occur independently and that not every chromosomal region produces a reciprocal effect when the opposite duplication is considered.

If a specific chromosomal region is responsible for the defective development of uniparental embryos, early lethality should be observed upon uniparental duplication. Only two chromosomal regions are associated with early lethality. Imprinted genes residing on proximal 6 may contribute to parthenogenetic failure (Figure 2). Little is known about maternal duplication for proximal 6 (MatDp(prox6)) except that it is embryonic-lethal prior to day 11.0 of gestation. Genes located on distal 7 may affect the survival of androgenotes as paternal

duplication of distal 7 (PatDp(dist7)) is embryonic-lethal around day 9.5 (Beechey *et al*., 2003). These embryos lack spongiotrophoblast and possess a thickened giant cell layer (McLaughlin *et al*., 1996). This phenotype is very similar to that of *achaete-scute homologue 2* (*Ascl2*) maternally deficient embryos (Guillemot *et al*., 1995). Mutant placentas display an increase in giant cells and a deficiency of proliferating spongiotrophoblast that leads to placental failure and lethality.

Three other imprinted genes in the region may also play a role in androgenetic placental development, *pleckstrin-homology domain A2* (*Phlda2/Ipl/Tssc3*), *cyclin-dependent kinase inhibitor 1C* (*Cdkn1c*), and *insulin-like growth factor 2* (*Igf2*). *Phlda2* and *Cdkn1c* are maternally transcribed genes, while *Igf2* is expressed from the paternal allele (Verona *et al*., 2003). Maternal deletion of *Phlda2* leads to placental overgrowth due to expansion of spongiotrophoblast and an increase in glycogen cells (Frank *et al*., 2002). Maternal deletion of *Cdkn1c* results in an increase in proliferating cells and placentomegaly (Takahashi *et al*., 2000). Lastly, deletion of the *H19* gene including the differentially methylated domain (DMD) results in biallelic expression of the adjacent *Igf2* gene that in turn produces somatic and placental overgrowth (Eggenschwiler *et al*., 1997).

Cdkn1c and *Igf2* have been suggested to have opposing effects on cell proliferation (Caspary *et al*., 1999). Double mutants of *Cdkn1c* and the *H19* DMD display exacerbation of the placental phenotype with overproliferation of trophoblast cells and disruptions in placental architecture, due to excess *Igf2* in the absence of *Cdkn1c* (Caspary *et al*., 1999). Thus, at least three genes on distal chromosome 7, *Acsl2*, *Cdkn1c*, and *Igf2*, are involved in cell proliferation and differentiation. These genes, as well as *Phlda2*, may play a pivotal role in aberrant proliferation of androgenetic cells and placental overgrowth. The lethality associated with PatDp(dist 7), however, occurs at a more advanced stage than the majority of androgenetic embryos, indicating the involvement of imprinted genes elsewhere in the genome.

In addition to lethality and placental structure defects, parthenogenetic and androgenetic cells exert parental-origin effects on growth and development of the embryo proper. Several chromosomal regions are associated with intrauterine growth retardation when maternally duplicated or with intrauterine growth enhancement when paternally duplicated (Figure 2). Targeted deletion studies have identified specific genes that contribute to these growth effects. Loss of maternal-specific expression of *growth factor receptor bound protein 10*, and of *insulin-like growth factor 2 receptor* (*Igf2r*) may account for the fetal and placental growth enhancement of PatDp(prox 11) and PatDp(prox 17) phenotypes, respectively (Beechey *et al*., 2003; Cattanach *et al*., 2004). Deficiency for *paternally expressed gene 3* (*Peg3*) and *Peg1* may be a factor in MatDp(prox 7) fetal and placental growth retardation and MatDp(subprox 6) fetal growth retardation, respectively (Beechey *et al*., 2003; Cattanach *et al*., 2004). In humans, disomy for maternal chromosome 7, which contains the orthologous *Peg1* imprinting domain, results in the development of Silver–Russell Syndrome (*see* Article 26, **Imprinting and epigenetic inheritance in human disease**, Volume 1), characterized by pre- and postnatal growth retardation, and a small, triangular face (Hitchins *et al*., 2001).

With respect to specific developmental abnormalities, genes within the *gene-trap locus 2* imprinted domain on distal chromosome 12 are likely contributors

to skeletal defects and liver enlargement in androgenotes. Paternal disomy for chromosome 12 causes placental growth enhancement, skeletal muscle enhancement, protruding thorax, abdominal extension, enlarged liver, costal cartilage defects, and hypo-ossification (Georgiades *et al*., 2000). In humans, patients with paternal disomy for chromosome 14 display similar phenotypic characteristics (Kurosawa *et al*., 2002). Uniparental duplications in mice represent suitable models for investigating human imprinting disorders originating from uniparental disomy (*see* Article 46, **UPD in human and mouse and role in identification of imprinted loci**, Volume 1).

Mouse embryos chimeric for PatDp(dist 7) share a large number of developmental anomalies produced by androgenesis (McLaughlin *et al*., 1997). These same pathogenic features are present in Beckwith–Weidemann Syndrome (BWS), an overgrowth disorder in humans (*see* Article 26, **Imprinting and epigenetic inheritance in human disease**, Volume 1 and Article 30, **Beckwith–Wiedemann syndrome**, Volume 1) involving the orthologous imprinting region (Eggenschwiler *et al*., 1997). Double mutants for *H19* and *Igf2r* and for *H19* and *Cdkn1c* in mice can recapitulate the majority of symptoms seen in BWS patients (Eggenschwiler *et al*., 1997; Caspary *et al*., 1999).

Collectively, these data signify that genes within multiple imprinted domains must act synergistically during embryonic development. There is experimental precedence for this. Individually, MatDp(prox 2) and PatDp(prox 11) affect growth but not viability. However, when inherited together, the combination is fatal (Cattanach *et al*., 2004). Additionally, mutations in the maternal *H19* DMD on distal 7 and the maternal *Igf2r* allele on proximal 17 produce an increased frequency and earlier onset of lethality (Eggenschwiler *et al*., 1997), demonstrating the combinatorial effect of imprinting lesions.

Further evidence for synergism comes from mutations of epigenetic regulators that result in loss of imprinting at multiple loci. *DNA methyltransferase 1* (*Dnmt1*) mutants are growth retarded, and die around embryonic day 9.0 (Lei *et al*., 1996). Their phenotype is reminiscent of parthenogenetic embryos and may arise from the requirement for *Dnmt1* in cell proliferation.

Conversely, *Dnmt3a*-, *Dnmt3a3b*-, and *Dnmt3L*-deficient embryos (*see* Article 32, **DNA methylation in epigenetics, development, and imprinting**, Volume 1) display a hyperproliferation phenotype similar to androgenetic fetuses, characterized by pericardial distension, neural tube defects, chorionic-allantoic fusion failure, thickened chorion, and hyperproliferation of secondary trophoblastic giant cells and yolk sac endoderm (Bourc'his *et al*., 2001; Hata *et al*., 2002; Kaneda *et al*., 2004). Defects in these embryos are due to loss of maternal imprints in oocytes. Interestingly, a recessive human disorder, familial biparental complete hydatidiform mole (phenotypically identical to androgenetic moles) occurs from a failure to acquire maternal-specific imprints (El-Maarri *et al*., 2003).

Bypassing in toto, a double dose of maternal imprinting marks greatly improves development. Gynogenotes generated by nuclear transfer of one nucleus that had and one nucleus that had not been maternally reprogrammed exhibited expression of genes that are normally transcribed from the paternal genome (Kono *et al*., 2004). However, development was highly variable, a factor likely dependent on the epigenetic state of each immature donor nucleus. Thus, the low rates of

viability further substantiate the requirement for a maternal and paternal genome in mammalian development and point to the complex etiology of parthenogenesis and androgenesis.

In conclusion, poor embryonic and extraembryonic development of uniparental embryos is attributed to misregulation of multiple genes governed by genomic imprinting and imprinted XCI. The most important of these genes likely have roles in cell proliferation and differentiation. Parthenogenetic and androgenetic embryos represent good models for investigating genomic imprinting and imprinted XCI. Further studies could provide insight into critical epigenetic events that occur during mammalian embryogenesis, including the stability of imprinted XCI and genomic imprinting in advanced stage uniparental embryos. Furthermore, as androgenetic embryos possess only paternally derived chromosomes, these embryos may be advantageous for determining the hotly contested question of whether X^P is reactivated in the zygote. Finally, given the similarity of developmental defects, investigation of uniparental embryos will be complementary to studies involving interspecific hybrids, somatic cell nuclear transfer embryos (*see* Article 34, **Epigenetics and imprint resetting in cloned animals**, Volume 1), and large offspring syndrome (*see* Article 35, **Imprinted QTL in farm animals: a fortuity or a common phenomenon?**, Volume 1) that together will further our understanding of epigenetics and mammalian embryogenesis.

Specialist Review

Imprinting in Prader–Willi and Angelman syndromes

Bernhard Horsthemke and Karin Buiting

Institut für Humangenetik, Universitätsklinikum Essen, Essen, Germany

1. Clinical, cytogenetic, and molecular findings in PWS and AS

The Prader–Willi syndrome (PWS) and the Angelman syndrome (AS) are well known examples of human diseases involving imprinted genes. PWS is characterized by neonatal muscular hypotonia and failure to thrive, hyperphagia and obesity starting in early childhood, hypogonadism, short stature, small hands and feet, sleep apnea, behavioral problems, and mild to moderate mental retardation. As shown in Table 1, patients with PWS have a deletion of the paternal chromosome 15 [del(15)(q11-q13)pat], maternal uniparental disomy 15 [upd(15)mat], or a maternal imprint on the paternal chromosome (imprinting defect). All three lesions lead to the lack of expression of imprinted genes that are active on the paternal chromosome only. At present, several such genes are known: *MKRN3*, *MAGEL2*, *NDN, SNURF-SNRPN,* and more than 70 genes encoding small nucleolar RNAs (snoRNAs) (see Figure 1 and below). The contribution to PWS of any of these genes is unknown, but it is generally believed that PWS involves the loss of function of two or more genes in 15q11-q13.

AS is characterized by microcephalus, ataxia, absence of speech, abnormal EEG pattern, severe mental retardation, and frequent laughing. Similar to PWS, the most frequent lesions in AS are a deletion, uniparental disomy, and an imprinting defect, but these lesions affect the maternal chromosome (Table 1). Therefore, it was concluded that AS involves a maternally expressed gene. On the basis of the finding of point mutations in patients with AS who do not have one of the above mentioned lesions, *UBE3A* has been identified as the gene affected in AS. Interestingly, *UBE3A* is imprinted only in the brain. There is one other gene in 15q11-q13 that is expressed from the maternal chromosome only: *ATP10C*. Although this gene is not expressed in AS patients with a deletion, uniparental disomy, or an imprinting defect, its role in AS is unclear (see also below).

2. Imprinted genes in 15q11-q13

MAKORIN3 (*MKRN3*, formerly *ZNF127*) is a ubiquitously expressed intronless gene, which encodes a polypeptide with a RING zinc-finger and multiple C_3H

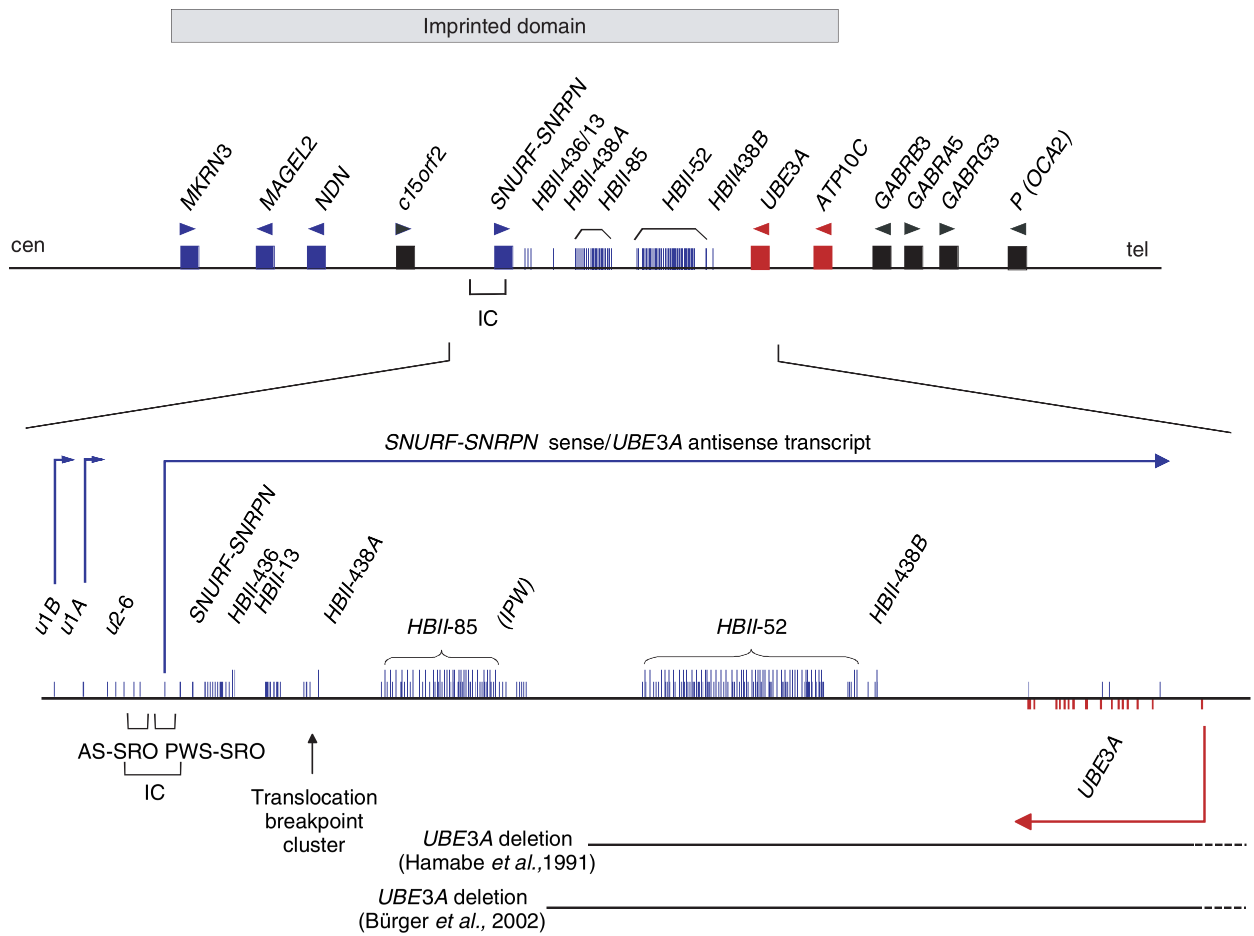

Figure 1 Physical map of the imprinted domain in 15q11-q13. Top: Gene order. Blue, paternally expressed genes; red, maternally expressed genes; black, biparentally expressed genes; arrowheads, orientation of transcription; IC, imprinting center; cen, centromere; tel, telomere. Bottom: structure of the *SNURF-SNRPN* transcription unit and the IC. U1B and u1A are alternative start sites. Short vertical blue lines, *SNURF-SNRPN* exons; long vertical blue lines, snoRNA genes; red vertical lines, *UBE3A* exons

Table 1 Genetic lesions in PWS and AS

Genetic lesion	PWS	AS
Deletion 15q11-q13	70% (pat)	70% (mat)
Uniparental disomy	28% (mat)	1% (pat)
Imprinting defect	1% (pat)	4% (mat)
Single gene mutation	–	5% (*UBE3A* mat)
Balanced translocation	Rare cases	–
Unknown	–	20%

zinc-finger motifs. Its function is unknown. *Mkrn3* knockout mice appear to be normal. Just telomeric to *MKRN3* are two other intronless genes, *MAGEL2* and *NECDIN* (*NDN*). Both genes encode proteins that are part of the melanoma-associated antigen (MAGE) protein family. *MAGEL2* is expressed only in the brain and placenta. Mouse models for *Magel2* are not yet available.

Whereas the human *NDN* gene is expressed in all tissues studied, with highest levels in brain and placenta, the murine *Ndn* gene is expressed predominantly in postmitotic neurons. The highest expression levels were found in the hypothalamus and other brain regions at late embryonic and early postnatal stages. It is upregulated during neuronal differentiation, and in vitro experiments have shown that overexpression of this gene leads to suppression of cell proliferation. Data obtained from different mouse models suggest that the loss of function of *Ndn* may contribute to respiratory distress and behavioral changes seen in patients with PWS (Ren *et al*., 2003).

The most complex locus in 15q11-q13 is *SNURF-SNRPN*. The original gene was found to consist of 10 exons, which encode two different proteins (Gray *et al*., 1999). Exons 1 to 3 encode SNURF (SNRPN upstream reading frame), a small polypeptide of unknown function, while exons 4 to 10 encode the small nuclear ribonucleioprotein N, a spliceosomal protein involved in RNA splicing in the brain. Mice lacking Snrpn appear to be normal (Yang *et al*., 1998). Knockouts of the promoter/exon 1 region of *Snurf-Snrpn* impair imprinting in the whole domain, because this region overlaps with the imprinting center (IC, see below).

In the past few years, many more 5′ and 3′ exons of *SNURF-SNRPN* have been identified. These exons have two peculiar features: they do not have any protein coding potential and they occur in many different splice forms of the primary transcript. Alternative transcripts containing novel 5′ exons were described by Dittrich *et al*. (1996) and characterized in detail by Färber *et al*. (1999). These transcripts start at two sites that share a high degree of sequence similarity. The 3′ exons are described in Runte *et al*. (2001). This analysis also showed that the *IPW* exons, which were previously thought to represent an independent gene ("imprinted in Prader–Willi syndrome"; Wevrick *et al*., 1994), are part of the *SNURF-SNRPN* transcription unit. Some of these splice variants are found predominately in brain and span the *UBE3A* gene in an antisense orientation.

Interestingly, the *SNURF-SNRPN* transcript also serves as a host for several snoRNAs, which are encoded within introns of this complex transcription unit. The genes are present as single copy genes (*HBII-13*, *HBII-436*, *HBII438A,* and *HBII-438B*) or as multigene clusters (*HBII-85* with 27 gene copies and *HBII-52*

with 47 gene copies) (Cavaillé *et al*., 2000; Runte *et al*., 2001). In contrast to other snoRNAs, which are usually involved in the modification of ribosomal RNAs, these snoRNAs do not have a region complementary to ribosomal RNA and might be involved in the modification of mRNAs. In *HBII-52*, 18 nucleotides are complementary to the serotonin receptor 2C mRNA (Cavaillé *et al*., 2000). It is possible that these snoRNAs are involved in the editing and/or alternative splicing of this mRNA.

In two unrelated families, a small deletion spanning *UBE3A* and the *HBII-52* gene cluster has been identified (Hamabe *et al*., 1991; Bürger *et al*., 2002). Whereas maternal transmission of the deletion leads to AS, paternal transmission is not associated with an obvious clinical phenotype. This excludes the *HBII-52* snoRNAs from a major role in PWS. The *HBII-85* gene cluster is distal to three balanced translocation breakpoints in patients with some features of PWS. As *HBII-85* is not expressed in one of the patients studied, these snoRNA may play a role in PWS. Knockout mice for the murine orthologs are currently being generated.

UBE3A encodes a ubiquitin-protein ligase that transfers ubiquitin to substrate proteins. Ubiquitin is a highly conserved 76 amino acid peptide that targets proteins for degradation. Thus, AS appears to result from a defect in proteasome-mediated protein degradation. *Ube3a* knockout mice (Jiang *et al*., 1998) serve as a model for AS.

ATP10C encodes a putative aminophospholipid translocase. Dhar *et al*. (2000) reported that maternal inheritance of deletions of the mouse *Atp10c* gene resulted in increased body fat. The obese phenotype was consistently observed in the mouse model for AS with paternal uniparental disomy as well as in a subset of sporadic AS ID patients (Gillessen-Kaesbach *et al*., 1999). However, loss of expression of *ATP10C*, which occurs in many patients with AS, is unlikely to play a role in the neurological features of this disease.

The murine orthologs of these genes map to mouse chromosome 7 (for a more detailed review on the human and murine genes see Nicholls and Knepper, 2001). Imprinted expression of the murine genes appears to be regulated in a similar way as in humans (see below).

3. Imprints

Paternal-only expression of *MKRN3*, *NDN,* and *SNURF-SNRPN* is associated with differential DNA methylation. Whereas the promoter/exon 1 regions of these genes are unmethylated on the expressing paternal chromosome, the silent maternal alleles are methylated (Glenn *et al*., 1993; Zeschnigk *et al*., 1997a). At the *SNURF-SNRPN* locus, a second differentially methylated region is found in intron 7. This region is preferentially methylated on the expressing paternal chromosome. The methylation status of the paternally expressed *MAGEL2* gene has not been thoroughly examined so far.

Differential DNA methylation can easily be detected with the help of methylation-sensitive restriction enzymes or by methylation-specific PCR (e.g., Sutcliffe *et al*., 1994; Zeschnigk *et al*., 1997b). AS and PWS patients with a deletion

15q11-q13, uniparental disomy 15, or an imprinting defect lack a methylated or an unmethylated band, respectively. Methylation analysis of *SNURF-SNRPN* is now the gold standard for testing patients suspected of having AS or PWS. Additional tests are necessary to distinguish between the different genetic lesions or, in AS patients with a normal methylation pattern, to search for a *UBE3A* mutation.

The promoter/exon 1 region of *SNURF-SNRPN*, which overlaps with the IC (see below), is the best studied region in 15q11-q13. In mice, the methylation imprint at this locus is clearly inherited from the gametes, but there is some controversy about the timing of methylation in human oogenesis. El-Maarri *et al*. (2001) have reported that in human oocytes *SNURF-SNRPN* is unmethylated and acquires a methylation imprint around or after fertilization. In contrast, Geuns *et al*. (2003) have found that oocytes are fully methylated at *SNURF-SNRPN*. This apparent discrepancy may be due to experimental problems or due to different protocols used for superovulation.

The methylation imprints are erased in primordial germ cells and newly established during later stages of gametogenesis. Interestingly, the acquisition of the maternal methylation imprint of the two alleles during oogenesis is asynchronous, at least in mice. Lucifero *et al*. (2004) found that the methylation imprint at the *Snurf-Snrpn* locus was initially established in preantral early growing oocytes on the maternally inherited allele and that the paternally inherited allele became methylated in more mature oocytes derived from antral follicles. These data indicate that the two alleles retain their parental identity after erasure of the parental imprints.

The paternally expressed snoRNA genes located between *SNURF-SNRPN* and *UBE3A* lack a direct methylation imprint. The snoRNAs are expressed from the paternal allele only, because they are processed from the paternally expressed *SNURF-SNRPN* sense/*UBE3A* antisense transcript. Thus, imprinted expression of the snoRNAs is indirectly regulated through *SNURF-SNRPN* methylation.

In vivo nuclease hypersensitive studies revealed that the two *SNURF-SNRPN* alleles do not only differ in DNA methylation but also in chromatin conformation (Schweizer *et al*., 1999). The paternal *SNURF-SNRPN* allele is associated with acetylated histones H4 and H3, whereas the maternal allele is hypoacetylated (Saitoh and Wada, 2000), in keeping with the general roles of DNA methylation and histone deacetylation to cooperate in transcriptional silencing. Xin *et al*. (2001) have demonstrated that the *SNURF-SNRPN* promoter/exon 1 region shows parent-specific complementary patterns of histone H3 lysine 9 (H3K9) and lysine 4 (H3K4) methylation. H3K9 is methylated on the maternal copy, and H3K4 is methylated on the paternal copy. They suggested that H3K9 methylation is a candidate maternal gametic imprint for this region. The authors also obtained evidence for a role of histone methylation in the establishment and maintenance of parent-specific DNA methylation (Xin *et al*., 2003).

In contrast to the paternally active *MKRN3*, *NDN,* and *SNURF-SNRPN* genes, the maternally active *UBE3A* gene lacks differential DNA methylation. Another striking difference is that imprinted *UBE3A* expression is tissue-specific. It has been proposed that paternal-only expression of a brain-specific antisense gene might prevent transcription of the paternal *UBE3A* gene (Rougeulle *et al*., 1998). A paternal deletion of the murine IC results in the loss of the antisense transcript

(Chamberlain and Brannan, 2001). As shown by Runte *et al*. (2001), the *UBE3A* antisense RNA is the 3′ end of the *SNURF-SNRPN* transcript, thus explaining its loss in mice and humans carrying a paternally inherited IC deletion. As the ultimate 3′ end of the *SNURF-SNRPN* sense/*UBE3A* antisense transcript has not yet been defined, it is possible that it extends into the *ATP10C* locus and plays a role in paternal silencing of this gene also.

In addition to DNA methylation and histone modification, the parental copies of 15q11-q13 differ in replication timing. Although there is some heterogeneity across this region, most of the paternal copy replicates before the maternal copy (Kitsberg *et al*., 1993). Asynchronous replication is erased during gametogenesis and maintained in the early embryo. Imprinting and replication timing are different processes, but appear to be regulated in a coordinate manner.

Another feature of 15q11-q13 is homologous association (LaSalle *et al*., 1996). A temporal and spatial association between maternal and paternal chromosomes 15 was observed in human T lymphocytes by three-dimensional fluorescence in situ hybridization. This association occurred only during the late S phase of the cell cycle. Cells from PWS and AS patients were deficient in association. This observation has not been confirmed by other groups.

4. Imprinting defects and the control of genomic imprinting in 15q11-q13

As shown in Table 1, approximately 1% of patients with PWS have a maternal imprint on the paternal chromosome and approximately 4% of patients with AS have a paternal imprint on the maternal chromosome. These imprinting defects are associated with silencing of the paternally expressed genes and the maternally expressed genes in 15q11-q13, respectively. Imprinting defects offer a unique opportunity to identify some of the factors and mechanisms involved in imprint erasure, resetting and maintenance. In 10–15% of cases, the imprinting defects are caused by a microdeletion affecting the 5′ end of the *SNURF-SNRPN* locus. These deletions define the 15q IC, which regulates imprinting in the whole domain (Sutcliffe *et al*., 1994; Buiting *et al*., 1995).

4.1. Imprinting defects caused by an IC deletion

To date, 32 deletions and one inversion affecting the IC have been reported. All the microdeletions found in patients with PWS affect the *SNURF-SNRPN* promoter/exon 1 region. Some of the deletions have occurred de novo on the paternal chromosome, but in most cases they have been inherited from the father. The deletions are without any phenotypic effect when transmitted through the female germline. The shortest region of deletion overlap (PWS-SRO) is 4.3 kb (Ohta *et al*., 1999). Segregation analysis suggested that this region is required for establishing or maintaining the paternal imprint in 15q11-q13. Studies of a PWS family in which the father is mosaic for an IC deletion on his paternal chromosome provided evidence that the deletion chromosome acquired a maternal methylation imprint in his

somatic cells. Identical findings were made in chimaeric mice generated from two independent embryonic stem (ES) cell lines harboring a similar deletion (Bielinska *et al*., 2000). Additional studies have shown that the sperm DNA from males with a maternally inherited PWS IC deletion has a normal paternal methylation imprint throughout human 15q11-q13, indicating that the maternal methylation imprint on the mutant maternal chromosome was successfully erased in the paternal germline and a paternal imprint established (El-Maarri *et al*., 2001). Thus, the incorrect maternal methylation pattern on the mutant paternal chromosome of patients with PWS and an IC deletion must have occurred after fertilization. These findings indicate that the PWS-SRO is not necessary for the establishment of the paternal imprint, but for maintaining the paternal methylation imprint during embryonic development, as proposed by Tilghman *et al*. (1998).

Targeted deletions in the mouse have revealed that the murine gene cluster on chromosome 7 is regulated in a similar way. The paternal transmission of a 42-kb deletion including the *Snurf-Snrpn* promoter/exon 1 region resulted in maternal imprint on the paternal chromosome (Yang *et al*., 1998). The mutant mice were smaller than their wild type littermates, exhibited muscular hypotonia and died within the first days of life. In contrast, paternal transmission of smaller deletion had little or no effect (Bressler *et al*., 2001).

In contrast to the PWS IC deletions, none of the IC deletions found in patients with AS affects the *SNURF-SNRPN* promoter/exon 1 region. Nevertheless, a shortest region of overlap (AS-SRO) could be defined (Buiting *et al*., 1999). The AS-SRO is 880 bp and maps 35 kb proximal to *SNURF-SNRPN* exon 1. Some of the deletions have occurred de novo on the maternal chromosome, but in most cases they have been inherited from the mother. The deletions are without any phenotypic effect when transmitted through the male germline and appear to have a role in establishing the maternal imprint in the female germline. The AS-SRO includes upstream exons u5 and u6 of the 5′ alternative *SNURF-SNRPN* transcripts (Dittrich *et al*., 1996; Färber *et al*., 1999). Dittrich *et al*. (1996) have suggested a model in which transcripts containing these exons are a major factor for setting up the maternal imprint. In this model, the AS-SRO is an imprintor that acts on the imprint switch initiation site (the PWS-SRO) to establish the maternal imprint.

The basic idea that the AS-SRO interacts with the PWS-SRO was confirmed by Perk *et al*. (2002), who showed that the maternal AS-SRO is essential for setting up the DNA methylation state and closed chromatin structure of the neighboring PWS-SRO. In contrast, the PWS-SRO had no influence on the epigenetic features of the AS-SRO. These results suggested a stepwise, unidirectional program in which structural imprinting at the AS-SRO brings about allele-specific repression of the maternal PWS-SRO. Transgenic mouse studies by Shemer *et al*. (2000) further supported this view, but challenged a role of alternative *SNURF-SNRPN* transcript in this process. The authors showed that a minitransgene with 1.0 kb of the human AS-SRO sequence fused to 0.2 kb of the mouse *Snurf-Snrpn* minimal promoter (homologous to the PWS-SRO) was appropriately imprinted after maternal and paternal transmission. These data suggest that the AS-SRO contains or overlaps one or more binding site for *trans*-acting factors. Although the AS-SRO is not differentially methylated in blood (Buiting *et al*., 2003), the demonstration of increased nuclease hypersensitivity on the maternal chromosome in the AS-SRO

region is consistent with the binding of *trans*-factors (Schweizer *et al*., 1999; Perk *et al*., 2002). Gel shift experiments as well as targeted deletions of different parts of the 0.2 kb *Snurf-Snrpn* minimal promoter of the transgene revealed the presence of five cis elements and putative trans-acting factors important for various steps in the imprinting process (Kantor *et al*., 2004).

It is unclear how the imprint spreads from the IC throughout the whole imprinted domain, but factors involved in chromatin conformation, such as heterochromatin-forming areas (matrix attachment regions, MARs) and transcription factor binding sites may play a role in this process. Genetic studies have shown that the IC is composed of an unusually high density of MARs with maternal-specific condensation, located in close proximity to the AS-SRO and PWS-SRO (Greally *et al*., 2000) and contains six “phylogenetic footprints”, DNA sequences of 7–10 bp that are conserved in the human and mouse *SNURF-SNRPN* promoter region (Ohta *et al*., 1999). Some of the latter sites are probably transcription factor binding sites for regulation of somatic expression of the gene, but one or more may also have IC regulatory function as sites for binding certain transcription factors during imprint erasure and resetting.

4.2. *Imprinting defects not caused by an IC deletion*

By analyzing more than one hundred PWS and AS patients with an imprinting defect, Buiting *et al*. (2003) have determined that in 85–90% of these cases the defect is not caused by an IC deletion, but that it is an epimutation (aberrant epigenetic state) that occurred spontaneously in the absence of DNA sequence changes. The apparent absence of point mutations, at least in the known critical elements of the IC (the AS-SRO and PWS-SRO) may indicate that the IC can tolerate small sequence changes or that it contains multiple, redundant elements. The latter notion is supported by the findings of multiple small IC sequence elements in the mouse (Kantor *et al*., 2004) (Figure 2).

Buiting *et al*. (2003) have also found that in PWS the imprinting defect was always on the chromosome 15 that was inherited from the paternal grandmother. This indicates that the paternal germline had failed to erase the maternal imprint so that the grandmaternal imprint was transmitted to the grandchild. This is the first demonstration of epigenetic inheritance in man.

In contrast, the imprinting defect in AS patients was on the chromosome 15 inherited from either the maternal grandmother or the maternal grandfather. This suggests that the maternal germline failed to establish a maternal imprint or that the maternal imprint was not maintained after fertilization. A postzygotic error in imprint maintenance is most likely in patients who are somatic mosaics. These patients, who comprise at least one-third of cases, have cells with an imprinting defect as well as normal cells. Methylation mosaicism is rarely observed in PWS. Using a novel quantitative MS-PCR assay, Nazlican *et al*. (2004) have found that the percentage of normal cells in peripheral blood of mosaic AS patients can vary considerably and that patients with a higher percentage of normal cells tend to have milder symptoms. Interestingly, some of these patients have an atypical

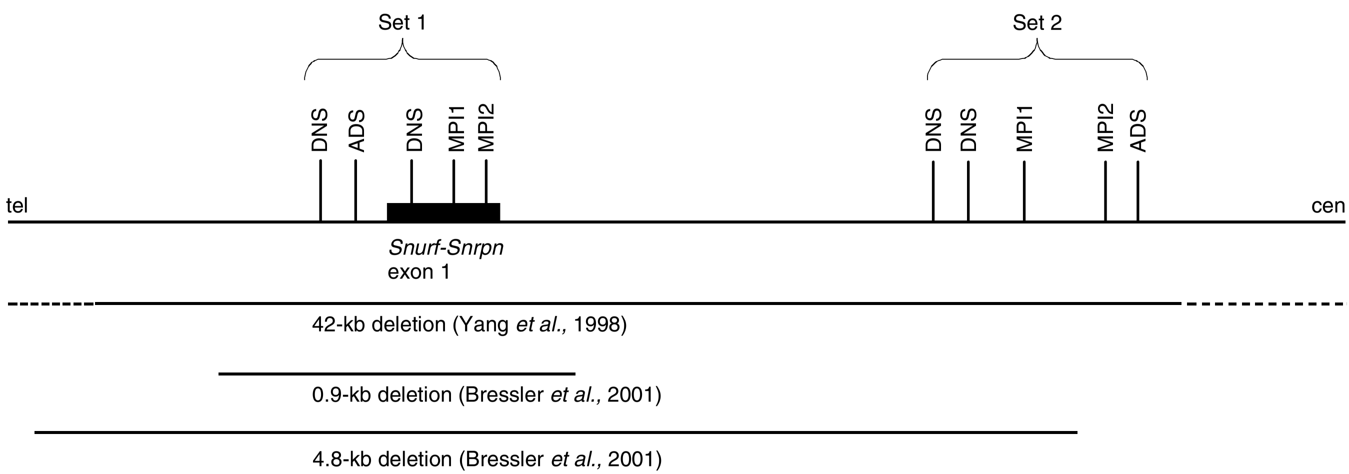

Figure 2 Sequence elements of the murine PWS-SRO. Set 1 overlaps *Snurf-Snrpn* exon 1 (black box). Set 2 is in intron 1. DNS, de novo methylation signal; ADS, allele discrimination signal; MPI, elements required for maintaining the paternal imprint (Reproduced from Kantor *et al*., 2004 by permission of Oxford University Press)

phenotype characterized by muscular hypotonia, early onset obesity and ability to speak (Gillessen-Kaesbach *et al*., 1999).

It is unclear, why, despite of an intact IC, the maternal imprint may not be established or be lost. Possible explanations include stochastic errors of the enzymatic machinery, genetic predisposition, and exogenous factors. A very critical period for imprint maintenance are the first few days after fertilization. Although methylation imprints normally survive the wave of global demethylation occurring during preimplantation development, it may occasionally happen that this protection fails in one of the cells of the preembryo. The methylation imprint may also be lost during later stages of development, if the methylation imprint is not copied onto the newly synthesized DNA strand after DNA replication.

In addition to stochastic errors, it is also possible that common sequence variants of the IC are associated with an increased risk of imprinting defects. These sequence variants may not impair the binding of trans-acting factors, but have a somewhat lower affinity to these factors, thus leading to a somewhat increased error rate. A study addressing this possibility has been initiated by the authors.

Last, but not least, exogenous factors may play a role. Reports on three AS patients conceived by intracytoplasmic sperm injection (ICSI) have suggested that assisted reproductive technology (ART) may increase the risk of imprinting defects (Cox *et al*., 2002; Ørstavik *et al*., 2003). The same concern was raised with regard to Beckwith–Wiedemann syndrome, another disease involving imprinted genes. Further studies are necessary to confirm these findings and to investigate whether hormonal stimulation, gamete manipulation, or culture conditions are the responsible factors. Ludwig *et al*. (2005) found that infertility per se and hormonal stimulation are associated with an increased risk of imprinting defects leading to Angelman syndrome.

Specialist Review

Beckwith–Wiedemann syndrome

Benjamin Tycko
Columbia University, New York, NY, USA

Marcel Mannens
University of Amsterdam, Amsterdam, The Netherlands

1. BWS: historical aspects and clinical features

In 1964, Beckwith and, independently, Wiedemann reported a syndrome of macroglossia and omphalocele, associated with adrenal cortical cytomegaly, fetal gigantism, and other abnormalities. The original abstracts and articles describing these cases have been reviewed recently, along with an interesting discussion of gigantism in folklore and early medicine (Beckwith, 1998). The Beckwith–Wiedemann syndrome (BWS, MIM130650), as this constellation of findings came to be named, is thus characterized by overgrowth of many organs during fetal development and, as documented by numerous subsequent reports, an increased susceptibility to childhood tumors. Abdominal wall defects, usually umbilical hernia or omphalocele, can be severe in some cases and require surgical repair after birth. These defects are probably a consequence of the organomegaly, aggravated by a primary defect in the development of the abdominal wall. Macroglossia is often prominent (Figure 1), and partial glossectomy to reduce the size of the tongue is another surgical procedure sometimes performed on children with BWS. In other cases in which glossectomy can be avoided, the jaws grow to accommodate the tongue, making the macroglossia less evident later in life. The kidneys are often increased in size, and they sometimes contain substantial collections of primitive metanephric cells, the so-called nephrogenic rests (Beckwith *et al*., 1990). No doubt, related to this histological abnormality, BWS is associated with a roughly 7% incidence of Wilms tumor, an embryonal kidney cancer arising from metanephric precursor cells that are defective in their ability to differentiate into mature epithelial structures (Li *et al*., 2002).

Generalized somatic overgrowth, producing a variable degree of gigantism in the neonate, often accompanied by placentomegaly, is another cardinal feature of BWS. In some cases, the overgrowth can be asymmetrical, producing so-called hemihypertrophy, which is probably more accurately termed *hemihyperplasia*. Lastly, ear pits and creases and facial nevus can be part of the syndrome (Figure 1), and neonatal hypoglycemia is found in about half of BWS cases for which this information is available. As described below, BWS is not a unitary disorder, but instead it has multiple genetic and epigenetic etiologies.

Figure 1 Macroglossia, nevus flameus, and ear creases in a child with BWS

2. Differential diagnosis of BWS: overgrowth syndromes

The clinical differential diagnosis of BWS includes other overgrowth disorders, notably the Simpson–Golabi–Behmel (SGBS), Perlman, and Sotos syndromes, and molecular tests are now a substantive aid in distinguishing these conditions. In Sotos syndrome (MIM117550), caused by deletions and point mutations in the *NSD1* gene encoding a nuclear regulatory protein, macrocephaly and a characteristic facial gestalt are major consistent features, while overgrowth and advanced bone age are sometimes but not always observed. The Weaver syndrome is a related disorder, and some Weaver syndrome cases have been reported to carry *NSD1* mutations, making this disorder allelic with Sotos syndrome (Rio *et al*., 2003). In contrast, SGBS (MIM312870), caused in most cases by mutations in the glypican gene *GPC3* (or in other cases the adjacent *GPC4* gene) encoding a cell surface proteoglycan, includes somatic overgrowth as a major consistent feature. Renal dysplasia, polydactyly, macrocephaly and coarse facial features, and placentomegaly are additional features of SGBS, which have been comprehensively discussed in the context of a mouse model, the *Gpc3* knockout, which largely mimics the human disorder (Chiao *et al*., 2002). Perlman syndrome (MIM267000), comprising renal hamartomas, nephroblastomatosis, and fetal gigantism, but not omphalocele, is also in the differential diagnosis of overgrowth. Facial dysmorphism and a high perinatal mortality are additional features of this syndrome, which may show autosomal recessive inheritance (Greenberg *et al*., 1986). Because of its rarity, Perlman syndrome has not yet been defined in molecular terms. In a very complete differential diagnosis, one could also include the Klippel–Trenaunay–Weber syndrome, Proteus syndrome, and even neurofibromatis, because of the hemihyperplasia in this condition, albeit due to vascular malformations. Isolated hemihyperplasia can be a BWS patient with minimal features of BWS. Such individuals have a high tumor risk (5.9%) and

should be offered tumor surveillance (Hoyme *et al*., 1998). Lastly, overgrowth of the fetus is common and well known in the setting of maternal diabetes, but this type of macrosomia does not include omphalocele, macroglossia, or disproportionate visceromegaly; that is, the organ weights, while increased, are appropriate for the overall body size.

3. Genomic imprinting in the BWS region of chromosome 11p15

In a broad sense, BWS maps to human chromosome band 11p15, a chromosomal region that contains a large number of imprinted genes. So, to understand the various BWS-associated molecular defects, it is helpful to review the structure and imprinting of this DNA region. The basic concept of genomic or parental imprinting is reviewed elsewhere in this volume (*see* Article 28, **Imprinting and epigenetics in mouse models and embryogenesis: understanding the requirement for both parental genomes**, Volume 1 and Article 32, **DNA methylation in epigenetics, development, and imprinting**, Volume 1); briefly, imprinting is an epigenetic process, occurring in gametogenesis, which marks certain genes for allele-specific, parent-of-origin-dependent, mRNA expression in the conceptus. A large body of evidence implicates DNA methylation at critical CpG-rich sequences as the fundamental epigenetic mark controlling imprinting in mammals. Such "imprinting centers", which are at most several kilobases in length, control the allele-specific expression of multiple flanking genes, which can be found dispersed in up to several megabases of flanking DNA. Imprinting centers are differentially methylated on the maternal versus paternal chromosome homolog, and are therefore alternatively referred to as "differentially methylated regions" or DMRs (not every differentially methylated DNA sequence is an imprinting center, but the examples discussed here do function in this capacity). As shown in Figure 2, there are two distinct imprinting centers in chromosome band 11p15, one immediately upstream of the *H19* gene (the *H19* DMR) and the other within an intron of the large *KCNQ1* gene (the KvDMR1element, also known as the *LIT1-associated DMR*). The *H19* DMR controls the allele-specific expression of *H19* and *IGF2*, while the KvDMRl element controls the allele-specific expression of a larger cluster of imprinted genes, including *CDKN1C*. Thus, chromosome band 11p15 contains two distinct "imprinted domains". A list of the imprinted genes in this chromosomal region, with their biochemical functions, is in Table 1, and the transcriptionally active and silent alleles, that is, the direction of imprinting, for several of the relevant genes are diagramed in Figure 2. Most of these genes are maternally expressed/paternally silenced (a pattern often referred to as "paternally imprinted"), but an important exception is the growth-promoting gene *IGF2*, which is imprinted in the opposite direction, paternal allele active/maternal allele repressed.

As proven by knockout experiments in mice, each of the two imprinting centers acts in cis to enforce imprinting of its flanking genes (Fitzpatrick *et al*., 2002; Leighton *et al*., 1995). Somatic cell genetics using human chromosomes with an engineered deletion of KvDMR1/LIT1 also supports this conclusion (Horike *et al*.,

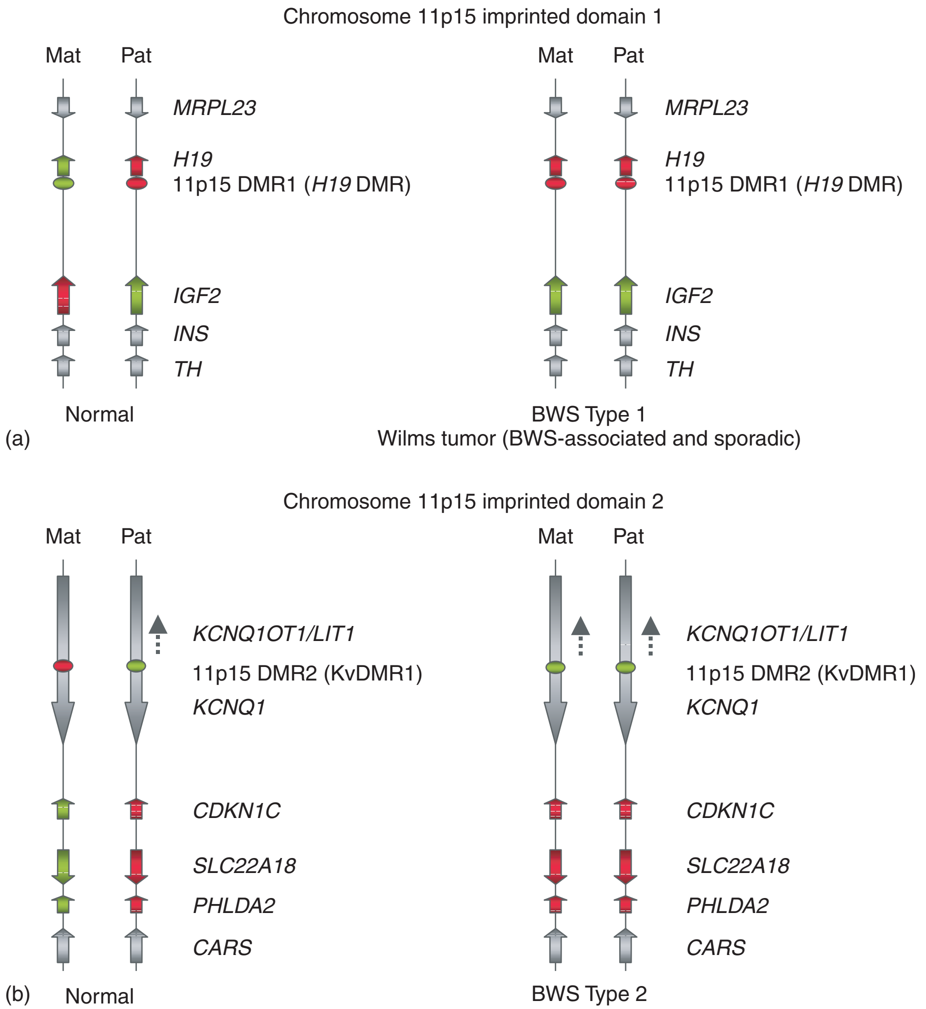

Figure 2 Two clusters of imprinted genes in the BWS-associated region of human chromosome 11p15. (a) The more distally located cluster of imprinted genes includes *H19* and *IGF2*. (b) The more proximally located cluster includes *CDKN1C* and several other imprinted genes. The red shading indicates lack of expression; green shading indicates active transcription. Gray shading indicates either lack of imprinting, weak tissue-specific imprinting or incompletely characterized imprinting. The cis-acting imprinting control elements (DMRs) are shown as ovals, with green indicating lack of CpG methylation and red indicating substantial CpG methylation. Directions of transcription are shown by the arrows. Mat: maternal chromosome; Pat: paternal chromosome. The abnormalities that lead to Type 1 and Type 2 BWS are indicated

2000). Several lines of data have led to a credible mechanistic model of how the *H19* DMR works to maintain the opposite allele-specific expression of *H19* and *IGF2* (Thorvaldsen and Bartolomei, 2000). As diagramed in Figure 3, this DMR acts as a chromatin insulator when it is unmethylated (maternal allele), and loses its insulator function when it is methylated (paternal allele). The unmethylated insulator, complexed to an insulator-binding protein called CTCF, blocks the

Table 1 Imprinted genes in the BWS-associated region of chromosome 11p15

Gene	Aliases	Expressed allele	Tissue-specific imprinting	Gene product
H19		Maternal	Many tissues	Nontranslated RNA
IGF2		Paternal	Many tissues	Trophic growth factor
INS		Paternal	Yolk sac	Insulin
ASCL2	*HASH2*	Maternal (stronger imprint in mice)	Extravillus trophoblast	Transcription factor for placental development
CD81	*TAPA1*	Maternal	Not known	Involved in signal transduction and lymphoma cell growth
TRPM5	*MTR1*	Paternal	Not known	Ion-channel
KCNQ1	*KvLQT1*	Maternal	Many tissues but not the heart	Ion-channel
KCNQ1OT1	*LIT1*	Paternal	Many tissues	Nontranslated RNA
CDKN1C	*p57*$^{\mathrm{KIP2}}$	Maternal	Many tissues	Cyclin-dependent kinase (cdk) inhibitor; regulates cell cycle and tissue growth
SLC22A18	*IMPT1* , *ITM*	Maternal	Many tissues	Membrane protein, putative multi drug resistance pump
PHLDA2	*TSSC3, IPL, BWR1C*	Maternal	Placenta and fetal liver	PH-domain protein regulating placental growth
OSBPL5	*ORP5*	Maternal	Placenta	Regulation of sterol metabolism
ZNF215		Maternal	Liver, lung, kidney, testis (not brain and heart)	Zinc-finger protein putative transcription factor

interaction of the *IGF2* promoter with downstream enhancer sequences while permitting the *H19* promoter to bind to these enhancers. In this situation (maternal allele), *H19* nontranslated RNA is produced, while *IGF2* mRNA is not. The opposite situation pertains for the paternal allele, in which CTCF binding is prevented by DNA methylation, and the *IGF2* promoter is therefore free to interact with the downstream enhancer elements. Precisely how the analogous KvDMRl element acts to maintain imprinting of its flanking genes is not yet clear. Like the *H19* DMR, this element is close to the initiation site for a nontranslated RNA (called *LIT1/KCNQ1OT1*). The function of this RNA is uncertain, but the KvDMR1 element is CG-rich, conserved in mammalian evolution, differentially methylated on the two alleles, and essential for imprinting of distant genes in cis, so it seems likely that some of the principles established for the *H19* DMR will also apply to KvDMR1.

4. Genetic and epigenetic etiologies of BWS

The phenotypic manifestations of BWS are variable, and this clinical heterogeneity can now be largely explained by an underlying molecular heterogeneity. As shown in Table 2, the majority of BWS cases can be assigned to one of several molecular categories. The observation that some individuals with BWS show mosaic uniparental paternal disomy of chromosome 11 on RFLP (restriction

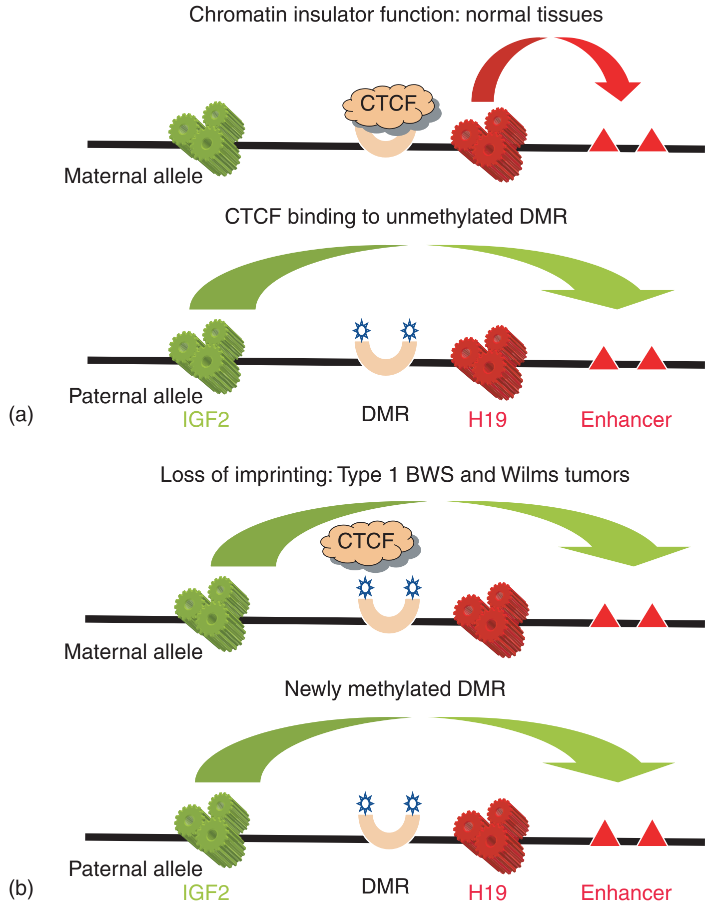

Figure 3 The chromatin insulator model for opposite imprinting of H19 and IGF2. (a) The insulator binding protein CTCF occupies the *H19* upstream DMR on the maternal allele, thereby preventing the *IGF2* promoter from interacting with the shared downstream enhancer elements, and enforcing monoallelic expression of *H19* RNA and *IGF2* mRNA from opposite alleles. (b) After de novo methylation of the DMR/insulator, *IGF2* becomes actively expressed from both alleles, and *H19* RNA is lost

fragment length polymorphism) analysis of blood or fibroblast DNA was an early indication of a role for imprinted genes in this disorder (Henry *et al*., 1991; Henry *et al*., 1993), and a substantial minority of cases, about 20%, can be attributed to this abnormality. Similarly, an important early finding was the existence of rare families in which BWS was transmitted by mothers but not fathers, and in which linkage could be established to markers on chromosome 11p15 (Koufos *et al*., 1989; Ping *et al*., 1989). In retrospect, most such cases are likely due to either mutations in *CDKN1C* (Hatada *et al*., 1996; Lam *et al*., 1999; O'Keefe *et al*., 1997) or recently described DNA microdeletions in the *CDKN1C* enhancer (Niemitz *et al*., 2004) or the *H19* DMR (Sparago *et al*., 2004). Another small subset of cases is accounted for by rare constitutional chromosomal translocations involving band 11p15, which

Table 2 Genetic and epigenetic defects causing BWS

Molecular defect	Dysregulated gene[a]	Proportion of cases	Clinical correlations
CDKN1C mutation	*CDKN1C*	3–5%	Omphalocele
KvDMR1[mat] loss of methylation	*CDKN1C*	50%	Omphalocele
			Rare tumors other than Wilms
H19[mat] gain of methylation	*IGF2*[b]	10%	Wilms tumors
Mosaic patUPD 11p15	*CDKN1C* and *IGF2*	20%	Wilms tumors
			Hemihyperplasia
Chromosomal translocations; chromosome band 11p15	*CDKN1C*	∼3%	Not known
	ZNF215 dysregulated		
Trisomy involving chromosome band 11p15	*IGF2*	5%	Overgrowth
			Wilms tumors
Unexplained (low level mosaicism?)	*CDKN1C?*	10–15%	Not known
	IGF2?		

[a]See the text for a discussion of additional chromosome 11p15 genes that may contribute to phenotypic variability in BWS.
[b]*H19* noncoding RNA also silenced in these cases.

also cause the syndrome only when transmitted maternally (Mannens *et al*., 1996). Some of these translocations have DNA breakage and rejoining close to KvDMR1, and presumably silence the expression of *CDKN1C* (11p15.5) (Lee *et al*., 1997b), while others influence the expression of a less well understood paternally imprinted gene, *ZNF215*, in chromosome band 11p15.4 (Alders *et al*., 2000). Currently, two patients define this more proximal BWS-associated chromosomal region; both demonstrated hemihyperplasia and minimal signs of BWS, and one developed a Wilms tumor.

In distinction to these genetic causes of BWS, two additional large groups of BWS cases are accounted for purely by epigenetic defects (Figures 2 and 3). In about 10% of cases, there is a pathological finding of gain of methylation (GOM) on the maternal *H19* DMR. This epigenetic lesion causes loss of imprinting (LOI) of *IGF2*, producing a double gene dosage of insulin-like growth factor II (Figures 2a and 3). "Nonsyndromic *IGF2* overgrowth disorder", also due to tissue mosaicism for GOM at the *H19* DMR, but with clinical hallmarks of gigantism and predisposition to Wilms tumor, but not macroglossia or abdominal wall defects, is a forme fruste of this category of BWS (Ogawa *et al*., 1993; Reeve, 1996). We refer this category of BWS as "Type 1" in Figure 2. The second epigenetic class of BWS, labeled "Type 2" in Figure 2, is attributed to loss of DNA methylation (LOM) on

the maternal allele of KvDMR1/LIT1 (Lee *et al*., 1999; Smilinich *et al*., 1999). As shown in Figure 2, this epigenetic defect leads to pathological biallelic expression of the *LIT1/KCNQ1OT1* untranslated RNA, and correlates with transcriptional downregulation (via gain-of-imprinting) of *CDKN1C* (Diaz-Meyer *et al*., 2003). Lastly, in about 10–15% of BWS no genetic or epigenetic defect is known. One possibility is that variable tissue mosaicism for LOM at KvDMR1 or GOM at the *H19* DMR may underlie some of these cases. Alternatively, some or all of these cases may actually be affected by Sotos syndrome, SGBS, or other BWS mimics.

5. Imprinted genes and growth regulation

From the data discussed above, and from mouse models (Caspary *et al*., 1999; Eggenschwiler *et al*., 1997), it is clear that the primary genes in the pathogenesis of BWS are *CDKN1C* and *IGF2*. These are good examples of imprinted genes that act to control growth – *IGF2* by encoding an antiapoptotic trophic factor with a positive net effect on tissue growth and *CDKN1C* by encoding a cyclin/cdk inhibitor with a negative net effect on cell proliferation and tissue growth. But the role of imprinted genes in mammalian growth regulation goes well beyond these examples. When this area was reviewed in 2002, there were nine examples of imprinted protein-coding genes proven by in vivo genetic data to control pre- or postnatal growth in mice and/or humans (Tycko and Morison, 2002), and an update from the recent literature reveals at least two additional examples (Charalambous *et al*., 2003; Moon *et al*., 2002). Strikingly, for each of these genes, the effect on growth correlates systematically with the direction of imprinting, with paternally expressed genes exerting a positive effect and maternally expressed genes a negative effect on net growth. This correlation is as predicted by the parental conflict theory of imprinting, which was first articulated in the early 1990s after the initial reports of opposite growth phenotypes in mice mutant for the oppositely imprinted *Igf2* and *Igf2r* genes (Moore and Haig, 1991).

Given the large number of imprinted growth-regulating genes in addition to *IGF2* and *CDKN1C*, it is interesting to consider whether aberrant expression of any of these genes might also contribute to overgrowth in humans. On chromosome 11p15 and the syntenic region of distal chromosome 7, in addition to *CDKN1C*, the *PHLDA2* gene (also known as *IPL/TSSC3*) is a bona fide growth suppressor, with placental overgrowth in *Phlda2* knockout mice and placental stunting in conceptuses engineered to overexpress this gene (Frank *et al*., 2002; Salas *et al*., 2004). Whether loss of expression of *PHLDA2* contributes to placentomegaly in BWS is an open question. While this also needs more study, the insulin gene (*INS*), closely upstream of *IGF2*, may well be overexpressed along with *IGF2* in the category of BWS with GOM at the *H19* DMR. Increased production of insulin may account at least in part for the finding of hypoglycemia in BWS (DeBaun *et al*., 2000), and since insulin can be mitogenic, such overexpression may also contribute to overgrowth. A related issue is whether any other imprinted chromosomal regions might contain genes that contribute to human overgrowth.

Uniparental maternal disomy for human chromosome 7 produces a growth-retardation syndrome, Silver–Russell syndrome, but we do not yet know of additional recurrent human chromosomal UPDs, other than those involving the chromosome 11p15 BWS region, that lead to overgrowth.

6. Cancer risk in BWS: epigenotype–phenotype correlation

Most cancers encountered in BWS are Wilms tumors (Bliek *et al*., 2004; Bliek *et al*., 2001; Gaston *et al*., 2001), but adrenal cortical carcinomas, hepatoblastomas, rhabdomyosarcomas, neuroblastomas, and other pediatric malignancies are also reported. Perhaps the most striking aspect of heterogeneity in BWS is the fact that cancer occurs only in a small subset, about 7%, of affected individuals. This percentage is lower than that seen in other well-studied human cancer syndromes, such as hereditary retinoblastoma, Li–Fraumeni syndrome, adenomatous polyposis coli and others, an observation that suggests either “incomplete penetrance” or molecular heterogeneity. The latter has proven to be correct, and a welcome recent advance has been the correlation of specific aspects of the BWS phenotype, including cancer risk, with the different molecular etiologies that underlie this disorder.

As early as 1999, a review of the literature suggested that predisposition to Wilms tumor in BWS is high in cases with Chr11p15 UPD or *H19* DMR GOM, and low or nonexistent in cases with *CDKN1C* mutations (Tycko, 1999). This conclusion was confirmed and strengthened shortly thereafter by a number of independent analyses of a large series, including a total of more than 250 molecularly characterized cases, which assessed these three classes of BWS, and also the large fourth category of affecteds with KvDMR1 LOM (Table 3). Frustratingly, the data are analyzed differently in each study, with some investigators choosing to describe the percentages of all tumor-bearing patients that have each molecular abnormality, and others describing the incidence of tumors in patients with a given molecular abnormality. The latter approach is easier to understand, so we have converted the data from each study to this uniform format in Table 3. The reader is also referred to a very recent combined European study of cancer risk in BWS (Bliek *et al*., 2004). These “meta-analyses” show that Wilms tumors, which in all of the series are the most common cancer, are increased in frequency only in those individuals that have BWS due to Chr11p15 UPD or *H19* DMR GOM. Since these two categories of BWS account for a minority of cases, this information nicely accounts for the limited Wilms tumor predisposition.

Larger series of cases will be needed to answer whether the rarer types of BWS-associated neoplasms, including adrenal cortical carcinoma, hepatoblastoma, and neuroblastoma are also specifically associated with a specific epigenotype in BWS. In fact, some of these non-Wilms neoplasms have been identified in BWS cases associated with the KvDMR1 imprinted domain: 2 neuroblastomas have been reported in children with *CDKN1C* mutations, and 2 hepatoblastomas, 2 rhabdomyosarcomas, and 1 gonadoblastoma were found in BWS-affecteds with KvDMR1 LOM (Lee *et al*., 1997a; Weksberg *et al*., 2001).

Table 3 Epigenotype–phenotype correlations in BWS

Study	Molecular category[a]	Tumor[b] (*n*) %	Exomphalos[c] (*n*) %	Conclusions

Nd: not described.

[a]*H19* GOM and KvDMR1 LOM refer to cases with these isolated molecular defects; cases with UPD are listed separately.

[b]Incidence of neoplasia within the indicated molecular category of BWS.

[c]Incidence of exomphalos or, generically, midline abdominal wall defects (exomphalos or umbilical hernia), within the indicated molecular category of BWS.

[d]This study reported 7 Wilms tumors and 1 hepatoblastoma in 113 individuals with BWS. Of these, 56 individuals were fully characterized by molecular criteria to assess tumor risk.

[e]This single *CDKN1C* mutant case, found in SSCP screening of 102 patients, had a maternally transmitted missense mutation, but was not further described. This case is not included in the percentages, which are based on 56 fully characterized cases.

[f]Six patients with Wilms tumor and somatic overgrowth, without classical BWS, were also analyzed. No *CDKN1C* mutations were found.

[g]Numbers are extracted from Table 2 of DeBaun *et al*. (2002) and percentages calculated. Please note that the table in this original publication lists percentages in a different format (% of all BWS-associated tumors accounted for by each category of BWS, rather than tumor incidence in a given category of BWS). Also, in extracting the data from that table, we have segregated the UPD cases, which have both *H19* GOM and KvDMR1 LOM from the non-UPD cases, which have one, but not both, of these molecular defects.

[h]Data are extracted from the text and Table 2 and Figure 3 of this publication. In extracting the data from Figure 3 of that publication, we have segregated the UPD cases, which have both *H19* GOM and KvDMR1 LOM from the non-UPD cases, which have one, but not both, of these molecular defects.

7. Developmental defects in BWS: epigenotype–phenotype correlation

The major category of BWS-affecteds with KvDMR1 LOM, or the rarer but seemingly equivalent genetic lesion of *CDKN1C* mutation, instead of developing Wilms tumors tend to show abdominal wall defects. As is true for the cancer correlations discussed above, the epigenotype–phenotype correlations for abdominal wall defects in all of the large case series analyzed to date are in complete agreement (Table 3).

8. Genetic and epigenetic mosaicism in BWS and Wilms tumor

Paternal UPD for chromosome 11p15 in BWS is found as tissue mosaicism (Slatter *et al*., 1994), consistent with the known lethal effect of complete paternal UPD for the orthologous chromosomal region in mice (Ferguson-Smith *et al*., 1991). But tissue mosaicism in BWS is not restricted to this molecular class and is also frequently observed in cases with GOM at the *H19* DMR or LOM at KvDMR1. In these cases, the epigenetic mosaicism is detected as incomplete

loss (KvDMR1) or gain (*H19* DMR and *H19* gene) of specific methylated bands on Southern blots after digesting the DNA with methylation-sensitive restriction enzymes. Whether asymmetrical tissue mosaicism can account for hemihyperplasia/hemihypertrophy in BWS is a difficult question. Mice with mosaic patUPD for the region corresponding to human chromosome 11p15 did not manifest asymmetrical growth and the hemihypertrophy seen in the two translocation cases of BWS with chromosome breakpoints in band 11p15.4 was not accounted for by mosaicism, since the translocations were constitutional (Alders *et al*., 2000).

As discussed above, tumor predisposition in BWS tracks with gain of DNA methylation at the imprinting center immediately upstream of the *H19* gene, and with paternal uniparental disomy. But this situation is not restricted to BWS: the same types of abnormalities are found as tissue mosaicism in the kidneys of a sizable group of sporadic Wilms tumor patients, who do not manifest the other features of BWS (Moulton *et al*., 1994; Moulton *et al*., 1996). In fact, this type of epigenetic mosaicism in the kidneys of children with Wilms tumor is a particularly clear example of a cancer-associated “field effect” determined by early developmental events (Tycko, 2003). What accounts for the de novo GOM in the H19 upstream DMR sequences early in development remains an important unsolved problem.

9. Causal role for epigenetic defects in BWS: discordance in twins

If epigenetic lesions are the primary cause of many cases of BWS, a strong prediction is that monozygotic twins might sometimes be found discordant for this disorder, that is, it should be possible to find rare but informative examples of individuals who share an identical DNA sequence throughout their genomes, but which are nonetheless discordant for the molecular and phenotypic features of BWS. In fact, the older literature contains several case reports of twins discordant for BWS, and a number of these examples were in monozygotic twins (“identical” being a misnomer in this situation) (Hall, 1996; Junien, 1992). The largest single study is a recent compilation of clinical and molecular data for 10 monozygotic twin pairs that were discordant for BWS (Weksberg *et al*., 2002). As predicted from the hypothesis that BWS is often purely epigenetic in etiology, each of the affected probands showed loss of DNA methylation at KvDMR1. These investigators postulated that there was a failure to maintain methylation of the paternal KvDMR1 allele early in postzygotic development, either coincident or shortly after the twinning event. In addition to this straightforward conclusion, there are two further aspects of BWS and twinning that remain to be explained: there is an excess of females over males among BWS-discordant twin pairs, and the frequency of monozygotic twins with BWS is greater than expected from the rate of twinning in the general population. A discussion of possible explanations for these observations, based on failure of proper subcellular localization and/or function of

the DNMT1 methyltransferase enzyme immediately prior to the twinning event, can be found in a recent review (Bestor, 2003).

10. BWS and assisted reproductive technology (ART)

Recent studies from BWS registries in the United States, England, and France have reported a total of 19 cases of this disorder occurring in children produced by in vitro fertilization or intracytoplasmic sperm injection (DeBaun *et al*., 2003; Gicquel *et al*., 2003; Maher *et al*., 2003). On the basis of the total number of cases surveyed, it has been estimated that slightly more than 4% of BWS in developed nations may be associated with assisted reproductive technology (ART). Since it is estimated that ART accounts for only about 1% of all births in these countries, there may be an increased risk of BWS after ART. The denominator in this calculation is uncertain, however, and larger surveys, in which the rate of BWS is studied in unselected pregnancies after ART, are needed. One prior study, concerning 61 pregnancies that were viable to term or late gestation following ART, found a single case of BWS (Olivennes *et al*., 2001).

While the statistical conclusions will need to be confirmed by larger studies, the available molecular data do provide some support for a causal connection between ART and epigenetic disorders. In particular, 18/19 of the reported ART-associated cases of BWS showed loss of methylation at KvDMR1, with only one case showing GOM at the *H19* DMR. This ratio deviates from the expected general distribution of molecular causes of BWS, and the data are suggestive of an ART-related failure of methylation of the maternal KvDMR1 allele, that is, an "oocyte problem" rather than a "sperm problem". Whether this mechanistic hypothesis can be validated in an experimental system, such as mice conceived by ART, remains to be seen, but further circumstantial support comes from reports of three cases of a second epigenetic disorder, Angelman syndrome, occurring after ART and all showing lack of appropriate DNA methylation of the maternal allele in the relevant chromosome 15 imprinting control region, the *SNRPN* DMR (Cox *et al*., 2002; Orstavik *et al*., 2003).

Specialist Review

Imprinting at the *GNAS* locus and endocrine disease

Lee S. Weinstein, Min Chen, Akio Sakamoto and Jie Liu
National Institutes of Diabetes, Digestive, and Kidney Diseases, National Institute of Health, Bethesda, MD, USA

1. Introduction

$G_s\alpha$ is a ubiquitously expressed G protein α-subunit that couples numerous receptors to the enzyme adenylyl cyclase and is therefore required for the intracellular cyclic AMP response to many hormones and other signaling molecules (Weinstein *et al*., 2001; Weinstein, 2004). *GNAS*, the gene encoding $G_s\alpha$ that is located at 20q13 is a complex imprinted gene that generates multiple gene products through the use of alternative promoters and first exons that splice onto a common set of downstream exons (exons 2-13, see Figure 1) (*see* Article 30, **Alternative splicing: conservation and function**, Volume 3). The mouse ortholog *Gnas* is located within a syntenic region within chromosome 2 and has very similar overall structure and imprinting patterns (*see* Article 46, **UPD in human and mouse and role in identification of imprinted loci**, Volume 1, Article 20, **Synteny mapping**, Volume 3, Article 47, **The mouse genome sequence**, Volume 3, and Article 48, **Comparative sequencing of vertebrate genomes**, Volume 3). The most upstream promoter generates transcripts for the chromogranin-like protein NESP55, which is structurally and functionally unrelated to $G_s\alpha$. The NESP55 coding region is fully encoded by its specific upstream exon, and $G_s\alpha$ exons 2-13 form part of the 3′ untranslated region of NESP55 transcripts (Ischia *et al*., 1997). The next promoter generates transcripts encoding the neuroendocrine-specific $G_s\alpha$ isoform XLαs, which is structurally identical to $G_s\alpha$ except for the presence of a long amino-terminal extension encoded by its specific first exon (Klemke *et al*., 2000; Pasolli *et al*., 2000). NESP55 and XLαs are oppositely imprinted (Hayward *et al*., 1998a,b; Peters *et al*., 1999). NESP55 is expressed only from the maternal allele and its promoter region is DNA methylated on the paternal allele, while XLαs is only expressed from the paternal allele and its promoter is methylated on the maternal allele (*see* Article 26, **Imprinting and epigenetic inheritance in human disease**, Volume 1 and Article 29, **Imprinting in Prader–Willi and Angelman syndromes**, Volume 1). The XLαs promoter region appears to contain a primary imprint mark where methylation is established during gametogenesis (Coombes

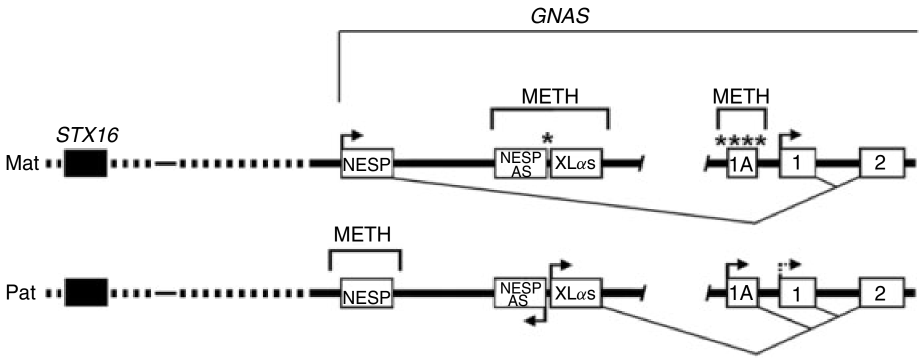

Figure 1 General organization and epigenotypes of the *GNAS* (and *Gnas*) locus. Maternal (Mat) and paternal (Pat) alleles of *GNAS* are depicted with alternative first exons for NESP55 (NESP), XLαs, exon 1A-specific untranslated mRNAs, and $G_s\alpha$ (exon 1) shown spliced to a common exon 2. Regions that are differentially methylated (METH) are noted above and splicing patterns are shown below in each panel. Transcriptionally active promoters are indicated by horizontal arrows in the direction of transcription. The dashed arrow for the paternal $G_s\alpha$ (exon 1) promoter indicates that $G_s\alpha$ expression from the paternal allele is suppressed in some tissues. The first exon for paternally expressed antisense transcripts is labeled as NESPAS. The location of two primary methylation imprint marks in *Gnas* is noted with asterisks. Common downstream exons 3-13 in the sense direction and downstream exons of the antisense transcript are not shown. A 3-kb deletion mutation within the *STX16* gene (black box), located 220 kb upstream of *GNAS* exon 1A, is associated with loss of exon 1A imprinting and familial PHP1B. The diagram is not drawn to scale

et al., 2003). This region also generates paternal-specific antisense transcripts that may be required for NESP55 imprinting, which has been shown in mice to not be established until after implantation (Hayward and Bonthron, 2000; Liu *et al*., 2000b; Wroe *et al*., 2000; *see also* Article 27, **Noncoding RNAs in mammals**, Volume 3).

The XLαs promoter is located ~35 kb upstream of the $G_s\alpha$ promoter (Figure 1). Studies in both mice and humans have shown $G_s\alpha$ to be imprinted in a tissue-specific manner. $G_s\alpha$ is equally expressed from both alleles in most tissues, but is expressed primarily from the maternal allele in certain hormone-target tissues (renal proximal tubules, a site of parathyroid hormone (PTH) action, thyroid, pituitary, ovary) (Germain-Lee *et al*., 2002; Hayward *et al*., 2001; Liu *et al*., 2003; Mantovani *et al*., 2002; *see also* Article 36, **Variable expressivity and epigenetics**, Volume 1). In some tissues (e.g., thyroid), expression from the paternal allele is only partially suppressed. The $G_s\alpha$ promoter is located within a CpG island that is euchromatic and unmethylated on both parental alleles despite the allele-specific differences in expression (Liu *et al*., 2000b; Sakamoto *et al*., 2004; *see also* Article 28, **The distribution of genes in human genome**, Volume 3 and Article 33, **Transcriptional promoters**, Volume 3). It has been shown in mice that allele-specific differences in $G_s\alpha$ gene expression are associated with differences in the extent of methylation of the lysine 4 residue of histone H3 within its first exon, a parameter that has been shown to be correlated with transcriptional activity in nonmammalian species (Sakamoto *et al*., 2004; *see also* Article 27, **The histone code and epigenetic inheritance**, Volume 1). Just upstream of the $G_s\alpha$ promoter is a differentially methylated region (DMR), which appears to be a primary imprint mark, as methylation of the maternal allele in this region is

established during oogenesis and maintained throughout development (Liu *et al*., 2000a,b). Within this region is another alternative promoter and first exon (exon 1A) that generates nontranslated mRNA transcripts only from the paternal allele (*see* Article 27, **Noncoding RNAs in mammals**, Volume 3). Both clinical and mouse studies suggest that this region (the exon 1A DMR) is necessary for tissue-specific imprinting of $G_s\alpha$ (see below).

2. Albright hereditary osteodystrophy

Albright hereditary osteodystrophy (AHO) is a congenital syndrome that is characterized by obesity, short stature, brachydactyly, subcutaneous ossifications, and, in some cases, neurobehavioral deficits (Weinstein *et al*., 2001). In most cases, AHO is associated with heterozygous loss-of-function mutations within or surrounding the $G_s\alpha$ coding exons, which may disrupt $G_s\alpha$ mRNA expression or protein expression or function (Aldred and Trembath, 2000). Consistent with the presence of a heterozygous null mutation, $G_s\alpha$ protein levels or bioactivity are reduced by $\sim$50% in membranes isolated from easily accessible tissues, such as erythrocytes and fibroblasts (Levine *et al*., 1983). Although these mutations could disrupt expression of other *GNAS* gene products, several lines of evidence point to $G_s\alpha$ haploinsufficiency as the likely molecular defect that is the cause of AHO. First, while all other known *GNAS* gene products are only expressed from one parental allele, the AHO phenotype is present in all patients with $G_s\alpha$ mutations, regardless of whether the mutation is inherited maternally or paternally. Second, some missense mutations are not predicted to affect NESP55 expression (Rickard and Wilson, 2003) and NESP55 deficiency in some patients with pseudohypoparathyroidism type 1B (PHPIB) does not lead to AHO (Liu *et al*., 2000a). Finally, mutations within $G_s\alpha$ exon 1, which would be predicted to only affect $G_s\alpha$ expression, also lead to the AHO phenotype. Some patients with $G_s\alpha$ null mutations develop a more severe ectopic ossification syndrome known as progressive osseous heteroplasia (Kaplan and Shore, 2000).

AHO patients who inherit the disease maternally (or have a de novo mutation on the maternal allele) also develop resistance to several hormones whose receptors activate $G_s\alpha$, including parathyroid hormone (PTH), thyrotropin, and gonadotropins, a condition also referred to as pseudohypoparathyroidism type 1A (PHP1A) (Davies and Hughes, 1993; Weinstein *et al*., 2001; Weinstein, 2004). In contrast, patients with paternal mutations develop AHO but do not develop hormone resistance, a condition also referred to as pseudopseudohypoparathyroidism. Studies in *Gnas* knockout mice showed a similar imprinted pattern of inheritance of renal PTH resistance and confirmed that this was due to tissue-specific $G_s\alpha$ imprinting (Yu *et al*., 1998; *see also* Article 38, **Mouse models**, Volume 3 and Article 41, **Mouse mutagenesis and gene function**, Volume 3). In renal proximal tubules (a major site of PTH action in the kidney), mutation of the active maternal allele leads to $G_s\alpha$ deficiency and PTH resistance (Figure 2). In contrast, mutation of the inactive paternal allele has little effect on $G_s\alpha$ expression or PTH sensitivity. The highly tissue-specific nature of the imprinting explains why the parent-of-origin effects are limited to a few hormone-signaling defects. This may also explain why

these patients fail to develop hormone resistance in other hormone-target tissues where $G_s\alpha$ is not imprinted (Weinstein *et al*., 2000).

3. Pseudohypoparathyroidism type 1B

PHPIB patients develop renal PTH resistance but do not develop the AHO phenotype (Silve *et al*., 1986). This disorder usually occurs sporadically but occasionally is familial. Like in PHPIA, the urinary cyclic AMP response to administered PTH is markedly reduced in PHPIB (Levine *et al*., 1983), implicating *GNAS* as a possible candidate disease gene for PHPIB as well. Despite this, erythrocyte $G_s\alpha$ levels and activity are normal in PHPIB (Levine *et al*., 1983; Silve *et al*., 1986), ruling out typical $G_s\alpha$ null mutations as the cause of PHPIB. Despite this, the familial PHPIB gene was mapped to 20q13 in the vicinity of *GNAS* (Juppner *et al*., 1998). Moreover, subjects within these kindreds only developed PTH resistance when the trait was inherited maternally, an inheritance pattern for PTH resistance similar to that observed in AHO patients with $G_s\alpha$ null mutations.

One mechanism that could explain the clinical features of PHPIB is the presence of a *GNAS* imprinting defect that results in both alleles having a paternal imprinting pattern or epigenotype. As $G_s\alpha$ is normally expressed primarily from the maternal allele in renal proximal tubules, the presence of a paternal epigenotype on both parental alleles would be expected to result in $G_s\alpha$ deficiency in proximal tubules and PTH resistance. In contrast, there should be little effect on $G_s\alpha$ expression in most other tissues, where $G_s\alpha$ is normally equally expressed from both parental alleles.

In most cases of familial PHPIB, a 3-kb deletion mutation is present within the closely linked *STX16* gene located upstream of *GNAS* in association with loss of maternal imprinting (methylation) of the exon 1A DMR (Bastepe *et al*., 2003; Liu *et al*., 2005b). Presumably, the deletion includes an imprinting control region that is critical for the establishment of exon 1A imprinting during oogenesis. In this scenario, maternal inheritance of the deletion leads to a paternal epigenotype within the exon 1A DMR on both parental alleles, which alters $G_s\alpha$ expression and hormone signaling (see below), while paternal inheritance of the deletion has no effect on exon 1A imprinting or $G_s\alpha$ expression, resulting in a clinically silent carrier state. The *STX16* deletion has no effect on imprinting of the intervening NESP55 and XLαs promoter regions, which suggests that exon 1A and NESP55/XLαs reside within independently regulated imprinted domains. In one family, PHPIB resulted from maternal inheritance of a $G_s\alpha$ missense mutation (deletion of isoleucine 382) that leads to selective uncoupling of $G_s\alpha$ from the PTH receptor (Wu *et al*., 2001).

Sporadic PHPIB is associated with *GNAS* imprinting defects in the absence of the *STX16* or any other known mutation (Bastepe *et al*., 2001b; Bastepe *et al*., 2003; Jan de Beur *et al*., 2003; Liu *et al*., 2000a; Liu *et al*., 2005b). In some sporadic cases, patients only have loss of exon 1A imprinting without the *STX16* mutation. Others have an imprinting defect where there is a paternal epigenotype in both parental alleles throughout the whole *GNAS* locus, and some have an imprinting defect involving exon 1A, NESP55, and the XLαs promoter, but not the XLαs

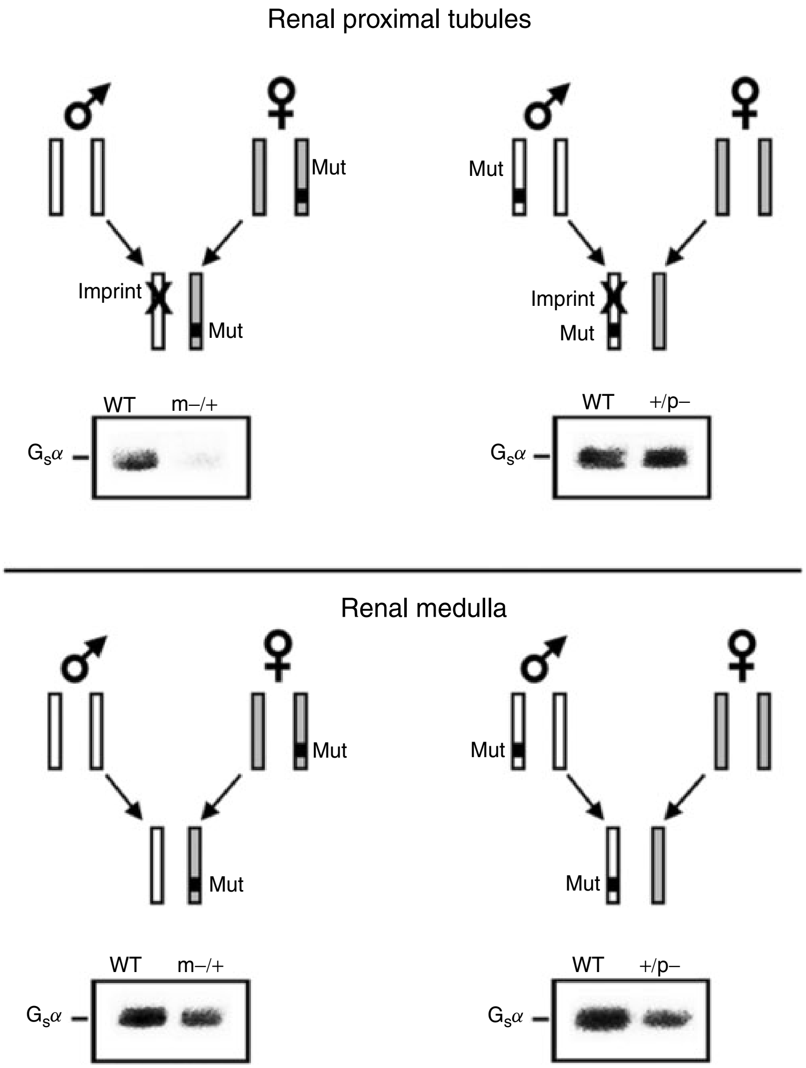

Figure 2 The effect of tissue-specific imprinting and heterozygous null mutations on $G_s\alpha$ expression in different tissues. In renal proximal tubules (upper panels), $G_s\alpha$ is paternally imprinted (denoted with X). Mutation (Mut) on the active maternal allele (left panel) leads to $G_s\alpha$ deficiency and PTH resistance while mutation on the inactive paternal allele (right panel) has little effect on $G_s\alpha$ expression or PTH sensitivity. Immunoblots of renal cortical membranes isolated from wild-type mice (WT) and mice with disruption of the *Gnas* maternal (m−/+) and paternal (+/p−) alleles respectively (Yu *et al*., 1998) confirms this imprinted pattern of $G_s\alpha$ expression. In most other tissues (lower panels), there is no $G_s\alpha$ imprinting and therefore both maternal and paternal mutations lead to ∼50% loss of $G_s\alpha$ expression (haploinsufficiency), as shown in immunoblots of renal inner medulla membranes from the same mice. This $G_s\alpha$ haploinsufficiency probably is the underlying molecular defect that leads to AHO in all patients with heterozygous $G_s\alpha$ mutations (both maternal and paternal) (Adapted from Weinstein *et al*. (2001) Endocrine manifestations of stimulatory G protein ∝-subunit mutations and the role of genomic imprinting. *Endocrine Reviews*, **22**, 675–705. © The Endocrine Society)

first exon. Patients with abnormal imprinting of the NESP55 promoter have loss of NESP55 expression due to methylation of the NESP55 promoter on both parental alleles without any obvious further clinical manifestations (Liu *et al*., 2000a). It is unclear whether the *GNAS* epigenetic defects in these sporadic mutations are the result of other underlying (and possibly de novo) mutations or rather result from the rare occurrence of the imprinting process going awry. One case of paternal uniparental disomy of 20q was associated with the expected *GNAS* imprinting abnormality along with PTH resistance and other clinical manifestations (Bastepe *et al*., 2001a; *see also* Article 19, **Uniparental disomy**, Volume 1).

The fact that PTH resistance in PHPIB is virtually always associated with loss of exon 1A imprinting provides strong support that the exon 1A DMR is a critical element in the regulation of tissue-specific $G_s\alpha$ imprinting. The fact that exon 1A and $G_s\alpha$ mRNA transcripts have a very similar pattern of tissue distribution (Liu, 2000b) makes it very unlikely that there is "competition" between these two promoters or that exon 1A transcripts themselves are involved in the $G_s\alpha$ imprinting mechanism. We have proposed that tissue-specific $G_s\alpha$ imprinting results from the presence of a cis-acting negative regulatory element (e.g., silencer or insulator) within the exon 1A DMR that is both tissue-specific and methylation-sensitive (Liu *et al*., 2000a; Weinstein *et al*., 2001). In the example shown in Figure 3, the exon 1A DMR contains a silencer. In renal proximal tubules, a tissue-specific repressor protein binds to the silencer and suppresses $G_s\alpha$ expression on the paternal allele, but is unable to bind to the silencer on the maternal allele because the site is methylated, allowing the maternal $G_s\alpha$ promoter to remain transcriptionally active. In most other tissues, exon 1A is still differentially methylated but there is no $G_s\alpha$ imprinting because the repressor is not expressed. In PHPIB, the methylation of exon 1A on the maternal allele is absent. In renal proximal tubules, the repressor can now bind to and inhibit $G_s\alpha$ expression from both parental alleles, resulting in $G_s\alpha$ deficiency and PTH resistance. In most other tissues, the loss of methylation has no effect on $G_s\alpha$ expression, because the repressor is absent. Support for this model is provided by studies in mice with deletion of the exon 1A DMR. Paternal, but not maternal, deletion of the exon 1A DMR results in $G_s\alpha$ overexpression in proximal tubules and lower circulating levels of PTH, indicative of increased PTH sensitivity, with little effect on $G_s\alpha$ expression in other tissues where $G_s\alpha$ is normally not imprinted (Williamson *et al*., 2004; Liu *et al*., 2005a; *see also* Article 38, **Mouse models**, Volume 3 and Article 41, **Mouse mutagenesis and gene function**, Volume 3).

$G_s\alpha$ is also partially imprinted in human thyroid, with ∼70–75% of the $G_s\alpha$ transcripts derived from the maternal allele (Germain-Lee *et al*., 2002; Liu *et al*., 2003; Mantovani *et al*., 2002). This explains why PHPIA patients (in whom the maternal allele is mutated) typically have mild to moderate hypothyroidism due to TSH resistance. One might predict that PHPIB patients would also have thyroid-specific $G_s\alpha$ deficiency, although to a lesser extent than in PHPIA, due to the fact that both alleles have a paternal epigenotype and therefore functionally behave as paternal alleles. Although TSH resistance has been considered to not be a feature of PHPIB, recent studies show that a significant number of patients with PHPIB and

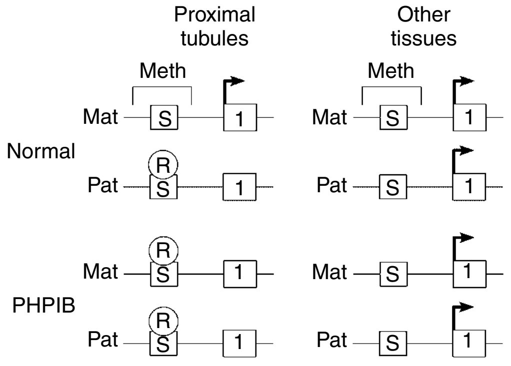

Figure 3 Proposed model for tissue-specific $G_s\alpha$ imprinting and pathogenesis of PHP1B. Maternal (Mat) and paternal (Pat) alleles of the exon 1A DMR-$G_s\alpha$ promoter region are depicted with a cis-acting silencer (S) within the exon 1A DMR and the first $G_s\alpha$ exon labeled as "1". Normally (upper panels), the silencer is methylated (Meth) on the maternal allele. In proximal tubules (left hand panel), a tissue-specific trans-acting repressor (R) binds to the silencer and suppresses $G_s\alpha$ expression on the paternal allele. The repressor fails to bind to the maternal allele due to methylation of the silencer, allowing the maternal $G_s\alpha$ promoter to remain active. In most other tissues (right hand panel), the repressor is not expressed and therefore the $G_s\alpha$ promoter remains transcriptionally active on both parental alleles. In PHP1B (lower panels), methylation is absent, allowing the repressor to bind to both alleles in proximal tubules, resulting in $G_s\alpha$ deficiency in this tissue. In most other tissues, $G_s\alpha$ expression is not affected owing to absence of the repressor

abnormal *GNAS* imprinting have evidence for borderline or mild TSH resistance (Bastepe *et al*., 2001a; Liu *et al*., 2003).

4. Potential role of $G_s\alpha$ imprinting on the clinical effects of activating $G_s\alpha$ mutations

Like all G proteins, $G_s\alpha$ is activated by receptors through release of bound GDP and binding of ambient GTP and is deactivated by an intrinsic GTPase that hydrolyzes bound GTP to GDP. Missense mutations in $G_s\alpha$ residues known to be catalytically important for the GTPase activity (arginine 201, glutamine 227) have been shown to be constitutively activating, and such dominant-acting somatic mutations are present in ~40% of growth hormone-secreting pituitary tumors (leading to acromegaly) and a small number of thyroid and other endocrine tumors (Lyons *et al*., 1990). More widespread distribution of arginine 201 mutations that presumably result from somatic mutation occurring during early embryonic development leads to the McCune–Albright syndrome, a condition characterized by the presence of precocious puberty, fibrous dysplasia of bone, café-au-lait skin lesions, and other endocrine and nonendocrine manifestations (Weinstein *et al*., 1991; *see also* Article 18, **Mosaicism**, Volume 1). Somatic arginine 201 mutations are also found in fibrous dysplasia of bone in patients who do not have the other manifestations of McCune–Albright syndrome. Recent studies show that $G_s\alpha$ is imprinted in the pituitary and that in almost all growth hormone-secreting pituitary

tumors harboring a $G_s\alpha$ activating mutation (both sporadic and in the setting of McCune–Albright syndrome), the mutation was present on the maternal allele (Hayward *et al*., 2001; Mantovani *et al*., 2004). These results suggest that the clinical manifestations of $G_s\alpha$-activating mutations may be affected by which parental allele harbors the mutation in tissues where there are allele-specific differences in $G_s\alpha$ expression.

Specialist Review

Developmental regulation of DNA methyltransferases

Diane J. Lees-Murdock and Colum P. Walsh
School of Biomedical Sciences, University of Ulster, Centre for Molecular Biosciences, Coleraine, UK

1. Introduction

It is well established that DNA methylation is important for maintaining genes in a transcriptionally repressed state (*see* Article 32, **DNA methylation in epigenetics, development, and imprinting**, Volume 1 and other chapters in this section). Due to the ability of methylation marks to be passed on to daughter cells after division, repression, once established, is very stable. Methylation patterns appear highly conserved in mice and humans; so to understand how and where methylation occurs in humans, extensive studies have been done in mouse, a more amenable experimental system. We will predominantly talk about results gleaned there, pointing out significant differences in humans where they may occur. Methylation in mice is used to repress a variety of different target sequences, some of which are parasitic in nature, such as endogenous retroviruses and retrotransposons (Bourc'his and Bestor, 2004; Walsh *et al*., 1998), and others that are endogenous genes required for normal development, such as the imprinted genes (Li *et al*., 1993, Article 26, **Imprinting and epigenetic inheritance in human disease**, Volume 1, Article 31, **Imprinting at the *GNAS* locus and endocrine disease**, Volume 1, Article 30, **Beckwith–Wiedemann syndrome**, Volume 1, Article 29, **Imprinting in Prader–Willi and Angelman syndromes**, Volume 1) and those on the inactive X chromosome (Csankovszki *et al*., 2001, Article 15, **Human X chromosome inactivation**, Volume 1, Article 41, **Initiation of X-chromosome inactivation**, Volume 1 and Article 40, **Spreading of X-chromosome inactivation**, Volume 1). Once methylation is established on the inactive X and the silent copies of imprinted genes, they remain stably shut down in each cell lineage during the lifetime of the organism due to the faithful copying of methylation patterns.

Methylation now appears to be established on unmethylated DNA de novo by the enzymes Dnmt3a and Dnmt3b (Kaneda *et al*., 2004; Okano *et al*., 1999); to do this, they require the presence of the cofactor Dnmt3L (Bourc'his and Bestor, 2004; Bourc'his *et al*., 2001; Hata *et al*., 2002; Webster *et al*., 2005). After methylation has been laid down, the pattern is faithfully copied to daughter cells by the activity of the maintenance enzyme Dnmt1 (Li *et al*., 1992), though Dnmt3a and Dnmt3b may also be required for maintenance of methylation at some sites in mouse

(Chen *et al*., 2003) and humans (Ting *et al*., 2004). Earlier knockout experiments suggested that Dnmt2, a protein containing conserved methyltransferase motifs, was unlikely to be involved in development (Okano *et al*., 1998) and the protein has recently been shown to encode a tRNA methyltransferase (Grace Goll *et al*., 2006) and so will not be discussed further here.

During gamete production in the mature animal, inactivation of the X chromosome and of the silent imprinted allele must be reversed, otherwise dosage compensation would fail and the offspring might inherit two inactive or two active alleles (*see* Article 15, **Human X chromosome inactivation**, Volume 1, Article 28, **Imprinting and epigenetics in mouse models and embryogenesis: understanding the requirement for both parental genomes**, Volume 1). As expected then, during embryonic germ cell development, DNA methylation undergoes radical reprogramming on single copy sequences (Hajkova *et al*., 2002; Li *et al*., 2004, *see also* Article 33, **Epigenetic reprogramming in germ cells and preimplantation embryos**, Volume 1). On the parasitic sequences, however, methylation does not change as much and most of these sequences appear to retain a high level of methylation throughout the embryonic life (Lane *et al*., 2003; Lees-Murdock *et al*., 2003).

2. Surfing the methylation wave

Removal of methylation on imprinted genes and the X chromosome to reset epigenetic memory appears to occur in the germ cells in the primordial gonads at around embryonic day 11.5 in mice, which is about a day after the germ cells arrive at the presumptive gonad following their migration from the base of the allantois (Ginsburg *et al*., 1990) (see Figure 1). When the cells first start arriving at e10.5, methylation is present on the silent copy of each imprinted gene (Hajkova *et al*., 2002; Li *et al*., 2004) and one X chromosome is inactive (Tam *et al*., 1994). By e12.5, methylation marks have been erased from imprinted genes in both male and female germ cells (Davis *et al*., 2000; Hajkova *et al*., 2002; Li *et al*., 2004) and the inactive X chromosome is also reactivated (Tam *et al*., 1994). It has been suggested that the erasure of imprints may be an active process due to the very short period in which it occurs (Hajkova *et al*., 2002). Some methylation is also lost from repetitive DNA elements at this stage, but the bulk of *IAP*, *LINE1* and minor satellite sequences remain methylated (Hajkova *et al*., 2002; Lees-Murdock *et al*., 2003). Continued methylation of selfish elements may help prevent them from spreading in the germ line (Bourc'his and Bestor, 2004; Walsh *et al*., 1998), while methylation of nontranscribed repeats may also be important for genome stability (Hansen *et al*., 1999; Okano *et al*., 1999; Xu *et al*., 1999).

The repeat elements are rapidly de novo methylated in the male germ line between e15.5 and e17.5, whereas methylation of these sequences in the female germ line remains lower at this stage (Lees-Murdock *et al*., 2003). The timing of this event coincides with the onset of methylation of the paternally imprinted genes, *H19* (Davis *et al*., 2000) and *Rasgrf1* (Li *et al*., 2004) that is initiated at e17.5, but unlike the repeat sequences, which have become completely methylated by

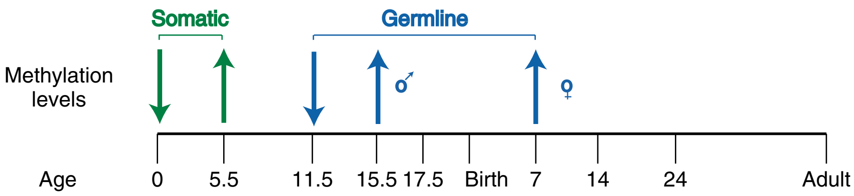

Figure 1 Timeline of development in the mouse with major methylation changes indicated. Embryonic or postnatal age in days is indicated below the line, with zero being the day of conception; embryonic ages are by convention given in half-day intervals. Mice are generally born at embryonic day 19 or 20, and then take three (female) to five (male) weeks to become sexually mature adults. Above the line is indicated the timing of *onset* of major methylation changes, decreases in methylation are a downward-pointing arrow, increases an upward-pointing one. Somatic (green) and germ cell (blue) lineages undergo separate methylation events, and de novo methylation begins at different times in the male and female germ lines. In male germ cells, methylation begins at approximately e15.5, but in females de novo methylation first occurs *postpartum* in the growing oocyte

e17.5, the paternally methylated imprinted genes do not become fully methylated until after birth (Bourc'his and Bestor, 2004; Davis *et al*., 2000; Kaneda *et al*., 2004; Li *et al*., 2004). In the female germ line, de novo methylation occurs in the growing oocyte for both repeats and imprinted genes (Lucifero *et al*., 2004).

In the preimplantation embryo as well, there is some evidence for ongoing changes in DNA methylation. In mice, the male pronucleus appears to become actively demethylated in the one-cell embryo, as shown by staining with antibodies to methylated cytosine (Santos *et al*., 2002) and by bisulfite sequencing of the *H19* gene (Olek and Walter, 1997), though this is not the case in all mammals (Beaujean *et al*., 2004). The female pronucleus is resistant to this active demethylation but becomes demethylated passively during cleavage divisions (Olek and Walter, 1997; Santos *et al*., 2002). *IAP*s, but not *LINE1* elements, are maintained at high methylation levels throughout this period (Lane *et al*., 2003; Walsh *et al*., 1998). After implantation, methylation levels overall appear to increase again (reviewed in (Yoder *et al*., 1997)). For single copy genes, the timing of methylation and its extent depends completely on the individual gene, since some do not become methylated at all, while some only become methylated when cell lineages become more firmly established, or during tumorigenesis (Jones and Baylin, 2002; Walsh and Bestor, 1999).

It is clear therefore that methylation must be tightly regulated to ensure that it is established and maintained correctly at the appropriate times and also to prevent maintenance or de novo methylation from occurring when cells are being reprogrammed in the germ line and in early development. In theory, this could involve proteins which bind to transcriptional control regions and either attract or prevent DNA methylation. As yet only a few candidates for such factors have been identified (Fedoriw *et al*. 2004; Suzuki *et al*., 2005), but this number would be expected to grow. Alternatively, control of when and where the cytosine methyltransferases themselves are expressed should also allow restriction of methylation to specific periods. There is good

evidence that this latter control mechanism is also used and here we review known mechanisms used to limit DNA methyltransferase expression during development.

3. Use of alternative promoters

One method used for restricting methyltransferase expression is by utilizing alternative promoters specific for particular cell types. This phenomenon was first seen at the *Dnmt1* locus in mouse, where it was discovered that three types of transcripts could be produced (Mertineit *et al*., 1998), originating at separate promoters that were active in different cell types (Figure 2). One promoter drives transcription of a full-length protein, Dnmt1^{s}, in all somatic cells. However, in the mouse testis, a separate promoter is used to drive expression specifically in the pachytene spermatocytes. This transcript (*Dnmt1*^{p}) is longer than the somatic form, but contains many upstream Open Reading Frames (ORFs) before the main protein-coding ORF, which are thought to inhibit protein expression (Mertineit *et al*., 1998). Supporting this view, the pachytene transcripts are not associated with polysomes and the protein cannot be detected in these cells (Jue *et al*., 1995). A recent report suggests that this transcript may also be active in myoblasts and showed it could produce some protein in an in vitro transcription-translation (IVTT) system (Aguirre-Arteta *et al*., 2000); however, the ability of the transcript to be

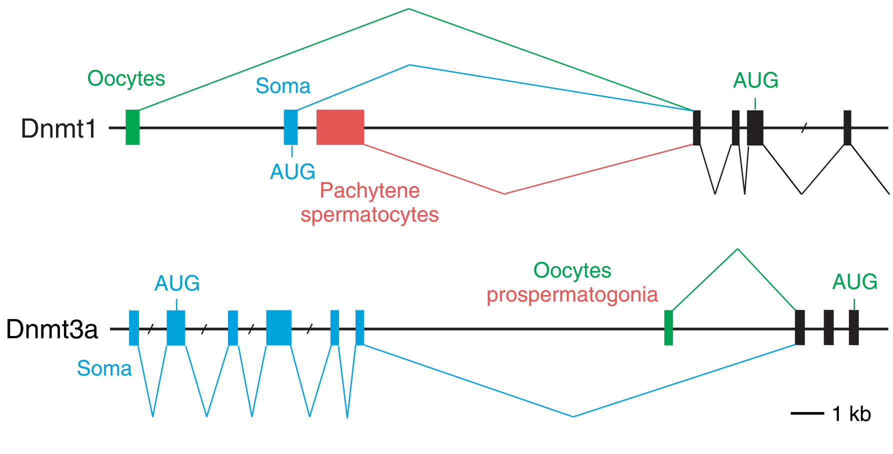

Figure 2 Alternative promoter and initiation codon usage for DNA methyltransferase genes in mice. The structures of the *Dnmt1* and *Dnmt3a* loci are shown schematically. Alternative promoters for *Dnmt1* direct the production of unique transcripts in oocytes (*Dnmt1*^{o}–green), pachytene spermatocytes (*Dnmt1*^{p}–red) and somatic cells (*Dnmt1*^{s}– blue), which differ only at the 5′ ends. The initiation codon used by *Dnmt1*^{s} is missing in *Dnmt1*^{o}, which instead initiates at an internal AUG codon to give a shorter protein with altered stability. Most evidence suggests that *Dnmt1*^{p} does not produce a protein. For *Dnmt3a*, one promoter (blue) produces a long transcript present at low levels in most tissues. A second promoter active in both germ lines produces a shorter mRNA (green). This also uses an internal initiation codon (indicated) to produce the smaller *Dnmt3a2* protein isoform. *Dnmt3a2* is also detected in somatic cells undergoing de novo methylation

translated may differ substantially in vivo from the IVTT system, so the balance of evidence is against a functional role for this form.

What then is it doing? The testis produces many alternative transcripts not seen in somatic cells (reviewed in (Kleene, 2001)). Some of these transcripts may reflect a need for a modified mRNA or an alternative protein in the highly specialized sperm cells. For other transcripts, intensive investigation by homologous deletion and other means have failed to find any function so far. It is possible that, like some alternative transcripts, the mRNA has no function and is a means of downregulating protein production while maintaining the locus in an active conformation. This might facilitate transcription of a functional isoform early in development or promote homologous recombination at this site. The gold standard test would be to carry out targeted mutation of the pachytene promoter or first exon and check for effects on male fertility. Existing *Dnmt1*-null mutant mice that target downstream exons generally do not survive to adulthood due to removal of the functional protein in somatic cells as well, so effects on male fertility are not known.

The third promoter for *Dnmt1* is active only in the oocyte and produces a longer transcript, but with a slightly shorter ORF (Mertineit *et al*., 1998). This shorter protein, Dnmt1^o, appears to be fully functional, however, and is the only isoform produced in the egg. This was demonstrated in knockout mice with homozygous deletion of the Dnmt1^o first exon and proximal promoter, which showed loss of Dnmt1^o in the egg, but normal expression of Dnmt1^s from implantation onward (Howell *et al*., 2001). Female mice with homozygous Dnmt1^o deletions were normal and produced eggs which also showed normal imprint establishment by meiosis II, showing that Dnmt1^o was not required for de novo methylation establishment on imprinted genes in the egg. However, these eggs did not go on to produce normal offspring, embryo loss postimplantation occurred and when examined, all imprinted genes had lost 50% of their methylation, due to the passive demethylation occurring during cleavage division (Figure 3) – normally, Dnmt1^o acts to prevent loss of methylation on imprinted genes at this stage. In mutants, the result is aberrant expression or silencing of the genes and since many are crucial for development, this is the likely cause of the embryonic lethality observed. The reason for the 50% loss is due to a nuclear trafficking event, discussed below. Although, Howell and colleagues did not observe any marked global depletion of methylation on *IAP* elements in Dnmt1^o knockout mice, later studies using Dnmt1^o knockouts coupled to a specific *IAP* insertion at the *agouti* locus suggest that Dnmt1^o may be required for maintenance of methylation in the preimplantation embryo on some *IAP*s as well (Gaudet *et al*., 2004). Confirming the importance of promoter switching for Dnmt, oocyte-specific promoters and mRNAs equivalent to the mouse Dnmt1^o also exist in human (Hayward *et al*., 2003) and opossum (Ding *et al*., 2003).

For Dnmt3a as well, an alternative promoter has been identified in both mouse and human that appears to be more active in germ cells and in postimplantation embryos, stages where de novo methylation is occurring (Chen *et al*., 2002). This promoter produces a shorter isoform called Dnmt3a2 that has been shown to have similar ability to rescue methylation in knockout mice as the longer Dnmt3a (Chen *et al*., 2003). The presence of a large number of pseudogenes in the rat

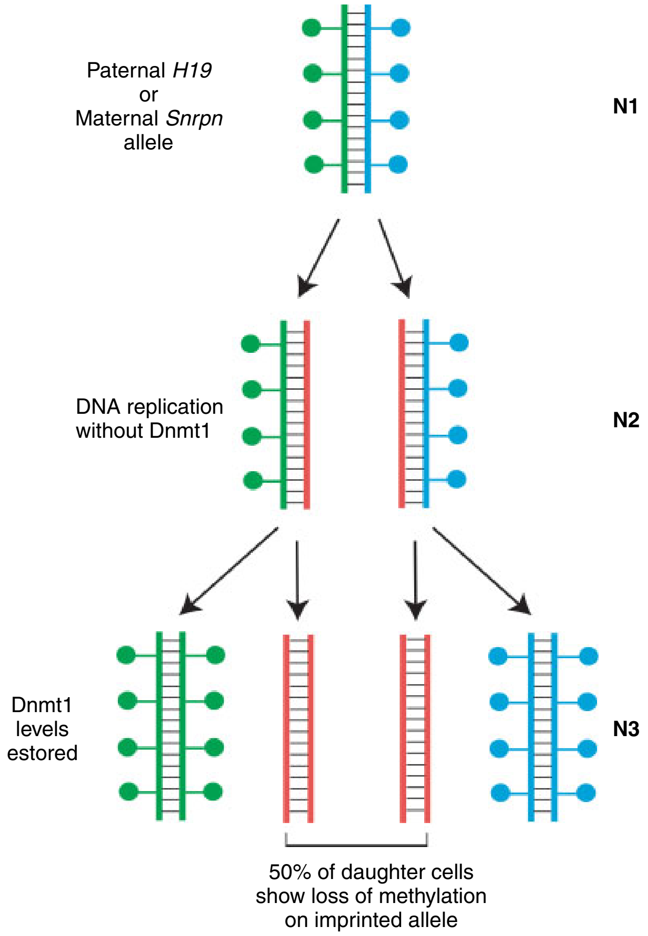

Figure 3 Consequences of a single cell duplication without efficient methylation maintenance activity. The DNA duplex encoding an imprinted gene is shown in the first generation (N1) at top. On the transcriptionally silent allele of imprinted genes, each strand of the DNA has methyl groups (circles). For *H19*, this is on the paternal chromosome (the maternal chromosome which is unmethylated is not shown, because its status will be unaffected by the loss of maintenance activity), whereas for *Snrpn*, it is the maternal copy of the gene that is methylated. On replication, the two strands of the helix are separated and act as templates for two new daughter strands (red). Methylation is added postreplication: if this does not occur, the daughter duplexes in N2 are hemimethylated. At the next round of replication, the unmethylated strands will act as templates for new duplexes. *Dnmt1* uses the parental strand as a template to add methylation to the newly synthesized strand and is not able to add methyl groups de novo. Even if maintenance activity is restored in N3, 50% of the cells will have lost methylation and will show dysregulation of imprinted gene transcription. This is what appears to occur in embryos, which develop from eggs lacking Dnmt1°, where both paternally and maternally methylated imprinted alleles show a 50% loss of methylation and aberrant transcription is seen. This gives an overall ratio of 75% unmethylated to 25% methylated strands, counting the unmethylated active alleles, which are unaffected in the mutant (not shown)

genome matching the shorter isoform, but not the longer, suggests that Dnmt3a2 is the ancestral transcript and that the additional exons found upstream in Dnmt3a may have been acquired later in evolution (Lees-Murdock *et al*., 2004). Cre-lox mediated mutation of an exon common to Dnmt3a and Dnmt3a2 specifically in germ cells demonstrated that the gene has a vital role in de novo methylation of imprinted genes in this lineage (Kaneda *et al*., 2004) though again, isoform-specific targeting would be needed to confirm that Dnmt3a2, rather than Dnmt3a, is more important in germ cells.

Despite identification of the putative promoter regions of the major players and some work on cloning and characterization (Aapola *et al*., 2004; Ishida *et al*., 2003; Ko *et al*., 2005; McCabe *et al*., 2005), on the whole little has been done to identify what signals they respond to and what transcription factors may play a role in regulating them.

4. Alternative splicing

One mechanism known to operate at the *Dnmt3b* locus to regulate protein production is the use of alternative splicing. This is a posttranscriptional level of control and thus simple genetic approaches are less useful to determine which factors regulate the process, and other experimental tools will be needed to work out the relevant details. A large number of mature transcripts of *Dnmt3b* exist in mouse and human (Chen *et al*., 2002; Lees-Murdock *et al*., 2005; Xu *et al*., 1999), differing in the splicing of a number of exons. Many of these are also capable of being translated into proteins in vivo (Chen *et al*., 2002), giving rise to different isoforms of the protein. While it has not yet been determined if all of these isoforms are functionally different, it is clear that in a number of these, vital motifs necessary for catalytic activity have been spliced out. Some of these variants have been tested for their ability to remethylate DNA and do indeed show little or no catalytic activity (Chen *et al*., 2003). Transcription of such mRNAs, which do not appear to produce functional proteins, is reminiscent of the situation for *Dnmt1* transcripts in the pachytene spermatocytes, and probably represents a way of downregulating the protein. Examination of the types of isoforms present at various stages of development can help to identify stages at which no functional isoforms are produced (Lees-Murdock *et al*., 2005; Sakai *et al*., 2004) and suggest that Dnmt3b2, a transcript lacking exon 10, may be most important for de novo methylation.

5. Nuclear import/export

Methylation relies on the proximity of the enzyme to its target in the nucleus of the cell and this can also act as a point of control for regulation of methylation. This was first demonstrated for Dnmt1, where studies showed that the protein undergoes complex cycles of entry and exit to the nucleus during development (Leonhardt *et al*., 1992). This form of control may be most important in the very earliest stages of development prior to implantation. As discussed above, in mouse oocytes Dnmt1

is produced from an alternative sex-specific $5'$ exon resulting in a truncated protein, Dnmt1^{o}. This short protein is the predominant form of Dnmt1 in oogenesis and early preimplantation development (Howell *et al*., 2001). Growing oocytes exhibit high levels of Dnmt1^{o} in the nucleus. As oogenesis proceeds, Dnmt1^{o} is either actively exported or simply blocked from entering the nucleus by factors retaining it in the cytoplasm and becomes sequestered subcortically in mature oocytes (Howell *et al*., 2001; Mertineit *et al*., 1998). Following fertilization, Dnmt1^{o} remains in the cytoplasm for the first two divisions, but moves back into the nucleus at the eight cell stage for a single cell division, before being again cytoplasmically localized at the 16-cell and morula stages (Carlson *et al*., 1992). At implantation, Dnmt1^{o} is downregulated and transcription of Dnmt1^{s} is activated in the blastocyst/egg cylinder and becomes localized to the nuclei (Trasler *et al*., 1996). Subcellular localization in the early embryo is most likely achieved by retention of Dnmt1^{o} by a factor in the egg cytoplasm rather than active nuclear export, as a tagged version of Dnmt1^{o}, when expressed in several different somatic cell lines, shows clear nuclear localization (Cardoso and Leonhardt, 1999) and embryos treated with a nuclear exporter inhibitor do not show accumulation of the protein in the nucleus (Doherty *et al*., 2002).

This complex choreography can perhaps best be understood in terms of what we know Dnmt1 is required for, i.e. maintaining existing methylation patterns. Restricting the protein to the cortex allows passive demethylation to occur during the cleavage divisions. The enzyme moves back in at the eight cell stage specifically to prevent loss of methylation on all imprinted genes (Howell *et al*., 2001). The fact that methylated alleles lose 50% of their methylation suggests that a single cell division is affected (see Figure 3); here then is an explanation for why Dnmt1^{o} must move back into the nucleus for a single cell division at the eight cell stage.

The mechanism causing the translocation is unknown but has been shown to be independent of DNA replication, transcription, protein synthesis, and compaction (Doherty *et al*., 2002). This unusual peripheral cytoplasmic localization of Dnmt1^{o} could be mediated by an Annexin V binding site present in the $5'$ end of the protein. Indeed, Dnmt1^{o} has been shown to bind to this protein (Ohsawa *et al*., 1996) and colocalize with it in preimplantation embryos (Doherty *et al*., 2002). Other binding sites have been described in both the amino terminus of the protein (Rountree *et al*., 2000) and the $3'$ untranslated region (UTR) of the mRNA (Lees-Murdock *et al*., 2004) that may be involved in subcellular localization, although their importance during development has not yet been fully elucidated.

Protein localization also appears to play a role in regulating the de novo methyltransferases' access to the DNA. During germ cell development, when imprints need to be removed after the germ cells colonize the gonad, Dnmt3b is excluded from germ cell nuclei while Dnmt3a is undetectable (Hajkova *et al*., 2002). At later stages, Dnmt3a is found in the male germ cells beginning at e15.5 (Lees-Murdock *et al*., 2005; Sakai *et al*., 2004), when methylation is occurring, while it is absent from the female germ cells at the same stage. Localization studies on Dnmt3a and Dnmt3b in the developing egg show similar patterns to that of Dnmt1, being localized to the nucleus at the earliest stages, but then moving out and becoming confined to the cortex in the MII oocyte (Lees-Murdock *et al*., 2004). In line with these observations, homozygous deletion of the Dnmt3a gene

results in the failure of de novo methylation in both the prospermatogonia and the growing oocyte (Kaneda *et al*., 2004). This knockout study did not determine which isoform, Dnmt3a or Dnmt3a2, is more important in germ cells, but a recent study indicates that Dnmt3a2 is the only form detected in the male germ cells during the period of de novo methylation (Sakai *et al*., 2004). A Dnmt3b deletion was reported not to effect methylation in germ cells (Kaneda *et al*., 2004), but no primary data was presented in the paper to support this, and additional work on this question will be of interest.

6. Protein stability

Finally, stabilization of Dnmt1 protein has recently been shown to be important for regulating its activity. The shorter oocyte form of the protein, when expressed in parallel with the somatic form in embryonic stem (ES) cells, showed greater stability than the latter (Ding and Chaillet, 2002). This increased stability would be an advantage during long-term storage in the egg. There is also a conserved KEN box in the middle of the protein which is a target for ubiquitin addition and subsequent proteasomal degradation of the protein: degradation occurs in the nucleus, and is prevented by cytoplasmic sequestration of the protein (Ghoshal *et al*., 2005). This may contribute to the increased stability of the oocyte form of the protein.

7. Importance of coordination

We now know that Dnmt1 appears to be almost exclusively involved in maintaining methylation patterns, after these patterns have been put on the DNA by the de novo enzymes Dnmt3a2 and Dnmt3b2. In the germ line (but not the soma), these latter appear dependent on the presence of Dnmt3L (see the article by Bestor and Bourc'his in this volume): in the absence of this protein, methylation fails to be properly established in either the female or male sex cells in mice (Bourc'his and Bestor, 2004; Bourc'his *et al*., 2001; Hata *et al*., 2002; Hata *et al*., 2006; Kaneda *et al*., 2004; Webster *et al*., 2005). It would therefore appear vital to coordinate expression of Dnmt3L and the de novo enzymes so that both an active enzyme and Dnmt3L are present in the nucleus at the same time. The mechanisms outlined above converge to provide only limited periods during development when Dnmt3L is actively transcribed and the active isoforms of the de novo enzymes are present in the nucleus (La Salle *et al*., 2004; Lees-Murdock *et al*., 2005; Sakai *et al*., 2004). Once established, these patterns of methylation are faithfully copied by Dnmt1 at every cell division: failure to do so for even a single cell cycle can lead to loss of imprints and embryo death, as evidenced by the Dnmt1^{o} knockout (Howell *et al*., 2001).

It is interesting to note that studies on human (Huntriss *et al*., 2004) and rhesus monkey (Vassena *et al*., 2005) found that *DNMT3L* was not transcriptionally active in the egg, but was turned on at the blastocyst stage. There was also one report indicating that maternal methylation imprints in human are established after

fertilization at the *SNRPN* gene (El-Maarri *et al*., 2001), though this was later disputed (Geuns *et al*., 2003). Further studies are needed to clarify the situation with regard to the timing of imprint establishment and the role of *DNMT3L* for maternal imprints in humans.

8. Concluding remarks

It is perhaps because of the powerful nature of gene repression through CpG methylation that such manifold layers of control have arisen to restrict methyltransferase expression during development. Although it can take as little as few hours for methylation to be established in germ cells, repression of the target genes can be efficiently maintained through decades of life for the organism. Evidently, with such power came the intricate series of checks and balances reviewed here.

Specialist Review

Epigenetic variation: amount, causes, and consequences

Elena de la Casa-Esperón
University of Texas at Arlington, Arlington, TX, US

Carmen Sapienza
Temple University, Philadelphia, PA, US

1. Introduction

The diversity of human phenotypes that we observe is the result of genetic and epigenetic variation and the interaction of these "biological" variables with environmental factors. Both large-scale and small-scale genome sequencing projects, as well as more recent efforts to define structural variation (copy number variation and subkaryotypic insertions, deletions and rearrangements), have resulted in an important initial description of the amount and type of genetic variation in the human genome. On the other hand, the scale of epigenetic variation in the human population is only beginning to be investigated.

Epigenetic variation may arise by diverse mechanisms but, at the molecular level, it reflects differences in the spatial configuration of chromatin and its interactions and function. Multiple biochemical processes (DNA methylation, histone methylation, acetylation, phosphorylation, sumoylation, etc.) are associated with these differences. One important consequence of this variability is the resultant variation in gene expression, although many other effects have also been described (see the following text).

In the same way that somatic mutations can be transmitted through successive cell divisions, epigenetic marks can change during the lifespan of an organism and also be transmitted somatically through subsequent cell divisions. In fact, the normal phenotypic diversity found between the different cell types of an organism is, with a few notable exceptions in the immune system, epigenetically controlled.

Interestingly, traits that result from particular patterns of epigenetic modification can also be transmitted between generations in some circumstances. The term "epialleles" has been coined to describe such different epigenetic states (Article 36, **Variable expressivity and epigenetics**, Volume 1). However, unlike DNA sequence changes, epigenetic modifications are often reversible at much higher frequencies than the mutation rate. This is an important characteristic, because epigenetic marks can be reset between generations and they can change in response

to the environment. Because epigenetic variation can also be genetically controlled, it constitutes a potentially important link between environmental and genetic factors (Cui *et al*., 1998; Nakagawa *et al*., 2001; Sandovici *et al*., 2003). Such a response to the environment could be mediated by metabolic changes that result in epigenetic modifications (Paldi, 2003; Waterland and Jirtle, 2004; Wolff *et al*., 1998). Consequently, epigenetic variability is not only a source of phenotypic plasticity in response to the environment, but these epigenetic alterations can also, potentially, be transmitted between generations, with very important implications in evolution (Rutherford and Henikoff, 2003; Sollars *et al*., 2003).

To better understand the relevance of epigenetic variation, we will discuss the extent (how much?), the origin (what are the causes?), and the implications (what are the consequences?) of this important source of phenotypic variation.

2. Epigenetic variation: how much?

2.1. *Epigenetic variation arises from multiple mechanisms*

It is difficult to estimate the precise extent of epigenetic variation because it occurs at multiple levels and as a result of multiple processes. The epigenetic variation resulting from inactivation of X chromosome provides a classic example of how multiple and distinct processes can give rise to very large fluctuation in phenotype among genetically similar or identical (Fraga *et al*., 2005) individuals. In human females (as in other female mammals), one of the two X chromosomes is inactivated by epigenetic means. Once one of the two X chromosomes is chosen for inactivation early in development, and the same X chromosome remains inactive in all descendants of that cell (Article 41, **Initiation of X-chromosome inactivation**, Volume 1). The inactive X chromosome becomes a cytologically visible heterochromatic body. This cytological manifestation of femaleness (the Barr body) is to a large extent (but not completely (Disteche, 1995)) transcriptionally inert. This means that each single cell expresses only one allele of most (approximately 85%) (Carrel and Willard, 2005) X-linked genes. If both X chromosomes have the same probability of being inactivated, the "average" women will have the paternal X chromosome inactive in 50% of her cells and the maternal X inactive in the remaining 50% of her cells. However, because the process of choosing the X chromosome for inactivation has a large stochastic component (Article 41, **Initiation of X-chromosome inactivation**, Volume 1), individual women will have different patterns of X-inactivation (Figure 1a). In fact, there is a minor fraction of females in whom >90% of the cells have the same X chromosome inactivated (Figure 1a). These females will have highly preferential expression of either maternal or paternal alleles of all X-linked genes affected by the inactivation process.

In addition to this partly stochastic, partly genetic variability in the fraction of cells in which a particular X chromosome remains active (see next section), there is also population-level and intraindividual variability in the extent of X-inactivation. It has been documented that a fraction of X-linked genes have escaped inactivation' (reviewed in Disteche, 1995). Interestingly, some genes are

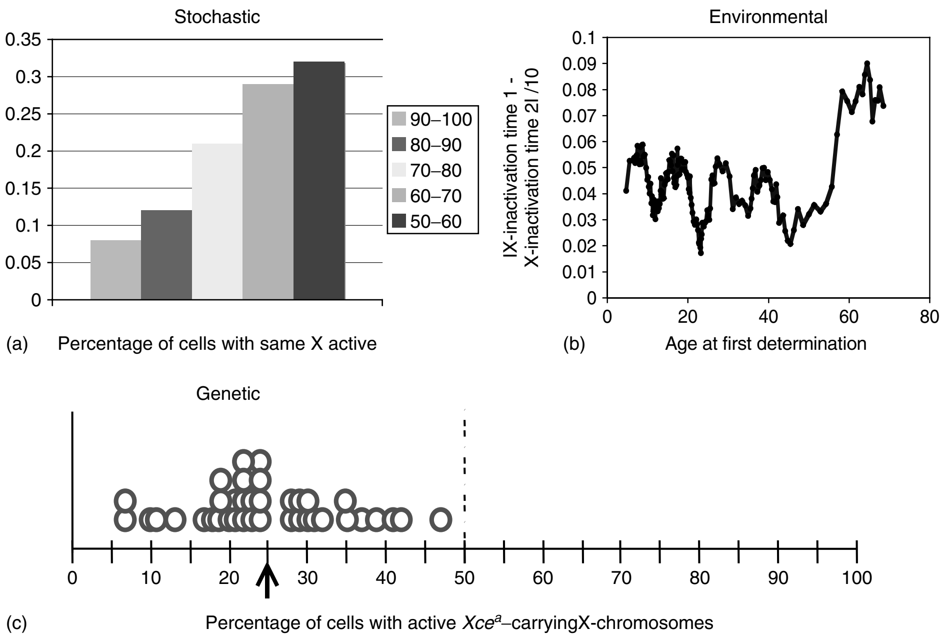

Figure 1 Origin of X-inactivation variation. (a) Much of the variation in the human results from the stochastic component of the X-inactivation choice process. Y-axis represents the fraction of women with the indicated percent of cells with the same X chromosome active (Naumova *et al*., 1996 and our unpublished data). Approximately one-third of women have either X chromosomes inactivated in one-half of their of cells (purple bar) and approximately 60% of women (purple bar plus green bar) have X-inactivation ratios between 50:50 and 70:30. However, approximately 7% of women have highly skewed patterns of X-inactivation, that is, greater than 90:10 (blue bar) in favor of the inactivation of a particular X chromosome. (b) Moving average of change in X-inactivation score in individual females (over nearly two decades; see Sandovici *et al*., 2004) as a function of age. Females who were greater than 60 years of age when the first sample was taken show significantly more variation over time than younger females. (c) Heritable effects on X-chromosome inactivation variation. Distribution of X-inactivation ratios in heterozygous Xce^a /Xce^c mouse females – each circle represents an individual female mouse (de la Casa-Esperon *et al*., 2002). The X-controlling element locus affects the probability that an X chromosome will become inactive, so that X chromosomes carrying the Xce^a allele have a higher probability of being inactivated than X chromosomes carrying the Xce^c allele. The observed mean X-inactivation ratio of this population of females is 25% of cells with an active Xce^a -carrying X chromosome

inactivated in some human samples, but escape inactivation in others (Carrel and Willard, 2005). In addition, the level of expression of such "escapees" also differs between samples (Carrel and Willard, 2005). Therefore, even genetically identical women (monozygotic twins) can differ in their mosaic pattern of X-inactivation, the number of genes that escape X-inactivation, and the levels of expression of some X-linked genes. In addition, some genes that have been inactivated may become reactivated as a function of age (Wareham *et al*., 1987) or other environmental factors, although not all X-linked genes appear equally susceptible to reactivation (Migeon *et al*., 1988; Pagani *et al*., 1990).

A similar variability in a long-term inactivation phenomenon has been observed for another class of monoallelically expressed genes located in the autosomes, the imprinted genes. Imprinted genes are expected to be expressed exclusively, or

nearly exclusively, from the paternal or the maternal copy (Article 37, **Evolution of genomic imprinting in mammals**, Volume 1). Several studies have shown that some imprinted genes (e.g., *IGF2*, *HTR2A* genes) are expressed from both alleles in a small fraction of normal individuals (Bunzel *et al*., 1998; Sakatani *et al*., 2001), while others (*IGF2R*) exhibit the reciprocal characteristic of being imprinted in only a small fraction of individuals (Xu *et al*., 1993).

Expression levels between alleles have been found to be variable for several imprinted genes in human tissues (Dao *et al*., 1998; McMinn *et al*., 2006), and have also been observed at nonimprinted autosomal genes. In fact, large-scale transcription profiling studies in humans have shown differential expression of alleles at a large proportion of loci (up to 54%, depending on the cutoff level of differential expression selected (Lo *et al*., 2003)) and, interestingly, the degree of difference in expression between particular alleles varies between individuals (Lin *et al*., 2005; Lo *et al*., 2003; Pant *et al*., 2006; Pastinen *et al*., 2004). Moreover, skewing of allelic expression is not necessarily in the same direction: in some individuals who are heterozygous for the same alleles, the allele that is preferentially expressed differs (Lo *et al*., 2003; Pastinen *et al*., 2004). This observation suggests that trans-modifiers and epigenetic variation are involved in the control of allelic differences in expression, in addition to polymorphisms in cis-regulatory sequences. Such extensive variation in allelic expression must have a large impact in generating phenotypic diversity.

2.2. *Variability in the biochemical "marks" associated with epigenetic variation*

The types of epigenetic marks that result in allelic variation in gene expression can be of diverse nature. The best known and most extensively investigated are covalent modifications of DNA and core histones. DNA methylation at CpG sites shows a degree of variability between different individuals at multiple loci. This is the case for imprinted genes like *IGF2/H19* and *IGF2R*, for which interindividual variation in methylation patterns has been observed in the differentially methylated regions associated with their expression (Sandovici *et al*., 2003). Interestingly, alterations in normal methylation patterns of these regions have been associated with loss of imprinting (LOI), a common observation in several types of cancer (Cui *et al*., 1998; Nakagawa *et al*., 2001). Another interesting example of interindividual variation at an imprinted gene is *PEG1*: this gene codes two isoform, one imprinted (isoform 1) and one expressed biallelically in multiple tissues (isoform 2). However, in a large subset of human placentae, isoform 2 allelic expression differences are observed, as well as interindividual variation in methylation of an associated CpG island (McMinn *et al*., 2006).

Interindividual variability in methylation patterns has been also described outside of imprinted genes or even protein coding regions: this is the case of methylation differences between humans that is observed in specific Alu repeated sequences (Sandovici *et al*., 2005). These observations reflect the fact that DNA methylation may have roles in addition to transcriptional control (de la Casa-Esperon and Sapienza, 2003; Pardo-Manuel de Villena *et al*., 2000; Sandovici *et al*., 2005).

Studies in other organisms also support the idea that variation in DNA methylation could be a widespread phenomenon. For instance, variation in cytosine methylation has been described in rRNA genes of natural accessions of the flowering plant *Arabidopsis thaliana* (Riddle and Richards, 2002), as well as in retrotransposons (Rangwala *et al*., 2006). Also, differentially methylated P1 pigment gene alleles have been observed in maize (Das and Messing, 1994). Importantly, studies in Arabidopsis have also shown that both natural and induced methylation changes can be transmitted to the offspring and result in developmental abnormalities in some instances (Kakutani *et al*., 1999; Rangwala *et al*., 2006; Riddle and Richards, 2005).

3. Epigenetic variation: what are the causes?

Epigenetic variation is the result of three types of processes: stochastic, environmental, and heritable. Variation in X-inactivation illustrates all three of these processes: during embryogenesis, one of the two X chromosomes is inactivated in each cell and clonally transmitted through successive mitotic divisions. Because this choice has a stochastic component (although some deterministic models are also capable of explaining the observations (Williams and Wu, 2004)), the X-inactivation patterns of a population of females approximates a normal distribution. The average female has about half of her cells with the maternal X chromosome inactive and half with the paternal X chromosome inactive. However, a small proportion of females show skewed patterns with a particular X chromosome being inactive in most cells (Figure 1a). Therefore, females are a mosaic for the expression of X-linked genes, and not even genetically identical females need show the same mosaic pattern.

The so-called skewing of X-inactivation is not always the rare consequence of the stochastic nature of the choice process. In some instances, skewing is the result of selection against X chromosomes carrying deleterious mutations, and the cell type-specificity of this skewing, as in X-linked agammaglobulinemia (skewing for inactivation of the mutant *XLA/BTK* allele in B-lymphocytes but not in T-lymphocytes), highlights the role of functional cellular selection (Fearon *et al*., 1987; reviewed in Belmont, 1996). In addition, skewing appears more common in older women, which suggests the contribution of environmental factors throughout their lifespan (Busque *et al*., 1996; Gale *et al*., 1997; Sharp *et al*., 2000). In this regard, X-inactivation seems to remain quite stable over many years during earlier ages (Sandovici *et al*., 2004) (Figure 1b). Many older females, however, exhibit substantial changes over the timescales at which younger females do not exhibit changes (Sandovici *et al*., 2004). In this regard, we have speculated (Sandovici *et al*., 2004) that acquired skewing of X-inactivation in older females may result from discontinuous or catastrophic processes that result in decreased numbers of stem cells or an age-related tendency toward bone marrow clonality or myelodysplasia.

Additionally, preference for the inactivation of a particular X chromosome can have a completely different origin compared to the selection for particular clonal cell populations or against disadvantageous mutations. Several studies in human and mice have shown that preference for X-inactivation can be heritable and genetically

controlled (Cattanach and Isaacson, 1967; Naumova *et al*., 1996, 1998; Plenge *et al*., 1997) In the mouse, the X-controlling element (*Xce*) is well known for its participation in the X-inactivation choice, so chromosomes carrying different alleles of *Xce* have different probabilities of being inactivated (Cattanach and Isaacson, 1967) (Figure 1c). Additional autosomal loci also participate in the genetic control of the choice of the X chromosome to be inactivated in mice (Chadwick and Willard, 2005; Percec *et al*., 2002, 2003). Moreover, parent-of-origin effects have also been observed in both mice (Takagi and Sasaki, 1975) and humans (Chadwick and Willard, 2005).

Stochastic, environmental, and genetic factors result in variability in X-chromosome inactivation and, consequently, generate a gamut of phenotypes for each of the X-linked genes, with multiple implications. The relative abundance of transcripts of each allele of any gene subject to X-inactivation reflects the fraction of cells with each of the two chromosomes active, as well as any allelic differences in expression that are intrinsic to specific alleles. Variations in such relative expression result in the spectrum of phenotypes observed in the population. For instance, a correlation between X-inactivation patterns and meiotic recombination levels (genomewide) has been described in female mice (de la Casa-Esperon *et al*., 2002). The biological importance of this trait (recombination levels) in the human population cannot be overestimated as it is a major determinant of female fecundity and reproductive lifespan. If recombination levels are controlled by gene/s in the X chromosome, then levels of recombination can change accordingly with the relative expression of different alleles of such gene/s. Because this is only one of the numerous genes in the X chromosome, the phenotypic diversity generated by similar phenomena related to X-inactivation processes is expected to be large in female mammals.

Similarly, epigenetic variability between individuals at multiple autosomal loci can be the result of multiple processes. Since erasure and establishment of epigenetic marks is a dynamic process that occurs during the lifespan of organisms, especially during gametogenesis and embryogenesis (reviewed in Latham, 1999; Mann and Bartolomei, 2002; Article 33, **Epigenetic reprogramming in germ cells and preimplantation embryos**, Volume 1), there is ample room for stochastic factors to contribute to the diversity of patterns observed. Environmental effects have also been described. Nutritional factors can induce epigenetic modifications such as changes in the expression of imprinted genes; moreover, maternal diet can affect the methylation status of transposable elements and the expression of nearby genes in mice (reviewed in Waterland and Jirtle, 2004). Examples of environmental effects have also been reported in rats, in which variations in maternal care behavior result in epigenetic changes in the offspring at the level of histone acetylation and DNA methylation of the consensus sequence for the NGFI-A transcription factor of the glucocorticoid receptor gene. Consequently, expression of this gene in the hippocampus can be modified by maternal care, which might be the basis for the changes in stress response observed in this gene in the offspring (reviewed in Fish *et al*., 2004). Environmental effects could be also the basis for the changes observed in epigenetic marks over time. DNA methylation patterns change with aging in a complex fashion, although overall hypomethylation has been observed in most vertebrate tissues (Mays-Hoopes *et al*., 1986; Richardson, 2003). For

instance, changes in the methylation profile of the c-*myc* proto-oncogene have been described during the aging process of mice. Because this is a gene involved in many tumor processes, similar temporal alterations of epigenetic marks might be part of the basis of the increasing incidence of cancer with age (Ono *et al*., 1986, 1989).

Finally, epigenetic diversity can be the result of heritable variants that affect the formation or stability of epigenetic marks. It has been observed that allelic differences in the expression of several genes are transmitted in families, although the patterns of transmission are variable (Pastinen *et al*., 2004; Yan *et al*., 2002). In some instances, the transmission of allelic imbalance is compatible with Mendelian inheritance, and even associated with transmission of particular polymorphisms (haplotypes), suggesting the participation of cis-acting elements in the regulation of allelic expression (Yan *et al*., 2002), whether they are of genetic or epigenetic origin. In fact, studies showing transmission of de novo induced methylation changes indicate that chromatin modifications, per se, are heritable (Kakutani *et al*., 1999; Stokes *et al*., 2002). Moreover, abnormal methylation patterns at the differentially methylated regions of the *IGF2/H19* and *IGF2R* imprinted genes have been found to cluster in families (Sandovici *et al*., 2003). Also, methylation levels at particular Alu repeated sequences show interindividual differences when the insertions were paternally versus maternally transmitted (Sandovici *et al*., 2005). In the case of imprinting defects, epimutations in an imprinting control region of human chromosome 15 have been associated with a substantial percentage of cases of the neurodevelopmental disorders Angelman and Prader–Willi syndromes (see Article 29, **Imprinting in Prader–Willi and Angelman syndromes**, Volume 1). Recent studies have shown that both cis- and trans-acting factors seem to increase the risk of conceiving a child with Angelman syndrome (AS) (Zogel *et al*., 2006). Trans-acting genetic elements have also been involved in changes in the imprinting status of the *Dlk1* gene in mouse brain (Croteau *et al*., 2005). In this case, reactivation of the normally silent maternal allele correlates with the methylation status of a differentially methylated region. Therefore, epigenetic information constitutes a code superimposed on the genetic information, thereby increasing phenotypic diversity. Much future research will no doubt focus on determining whether epigenetic variation makes a significant contribution to common "complex genetic disorders", such as diabetes, hypertension, schizophrenia, Alzheimer's disease and the like, in humans.

4. Epigenetic variation: what are the consequences?

Phenotypic diversity is the direct consequence of much epigenetic variation. As we mentioned before, epigenetic modifications can result in allelic expression imbalance within (differential expression levels) or between cells (monoallelic and mosaic expression). This, in turn, can result in phenotypic differences between cells, tissues, and/or individuals. The most obvious example is that of monozygotic twins: although genetically identical, numerous phenotypic differences appear during their life span. The same is true at the epigenetic level: recent studies have shown that differences in DNA methylation and histone acetylation between twins are present

throughout the genome (Fraga *et al*., 2005). Therefore, epigenetic differences could be the basis of many phenotypic discordances observed between twins, including their susceptibility to complex diseases (Wong *et al*., 2005).

4.1. Epigenetic variation and disease

Epigenetic variation is particularly important for genes involved in diseases. For instance, the fragile-X syndrome of mental retardation is associated with an expansion in the number of CGG repeats in the promoter and 5′ untranslated region of the *FMR1* gene on chromosome X. This expansion results in hypermethylation of the region and silencing of the *FMR1* gene (Hansen *et al*., 1992). Short expansions (premutations) do not have apparent phenotypic effects, while long expansions are observed in affected individuals. Notably, the severity of the disease ranges from severe mental retardation to only mild learning disabilities. It is possible that the observed gamut of symptoms depends, at least in part, on epigenetic differences, because variability in methylation in this region has been observed between and within individuals (Genc *et al*., 2000; Stoger *et al*., 1997) and changes in the CGG repeat length might also result in additional chromatin and transcriptional modifications.

Another interesting example of mosaicism has been observed in a small group of AS patients, in whom an imprinting defect silences the maternal copy of the *UBE3A* gene. However, some of these patients show mosaic maternal expression and methylation of this gene, which, again, suggests the possibility of an epigenetic effect on the observed variability in the severity of clinical symptoms (Nazlican *et al*., 2004).

Cancer has also been associated with epigenetic alterations, such as losses and gains of methylation and LOI (Feinberg *et al*., 1988, 2002; Cui *et al*., 2003; Jones and Baylin, 2002; Nakagawa *et al*., 2001). Interestingly, some of these alterations are also observed in normal tissues of the same individuals, as highlighted by the gain of DNA methylation in the imprinting control region upstream of *H19* in human Wilms tumors and in the non-neoplastic kidney parenchyma adjacent to these tumors (Cui *et al*., 1998, 2003; Moulton *et al*., 1994). Hence, epigenetic variation between individuals is probably involved in susceptibility to develop cancer as well as other genetic diseases. Moreover, since heritable epigenetic variation has been observed in many instances, it can actually play an important role in quantitative trait variation, and selection acting on such epialleles might result in rapid phenotypic changes, making it a formidable force in evolution (Rutherford and Henikoff, 2003; Sollars *et al*., 2003).

4.2. Epigenetic variation and development

Epigenetic variation also has important consequences in development and differentiation. A potentially important example of epigenetic changes as a result of environmental effects is the effects of culture conditions on the expression of imprinted genes in mouse embryos. It has been shown that some culture media

perturbs gene expression and results in aberrant methylation and expression of imprinted genes (Doherty *et al*., 2000; Mann *et al*., 2004; Rinaudo and Schultz, 2004). Although some of these abnormalities can be restored in the embryo proper (Mann *et al*., 2004), many persist in the extraembryonic tissues and can potentially affect the development of the embryo. In fact, several epidemiological studies suggest that assisted reproductive technologies (ART) might result in an increased frequency of diseases caused by imprinting defects, such as AS and Beckwith-Wiedemann syndrome (BWS) (Article 30, **Beckwith–Wiedemann syndrome**, Volume 1).

Despite the many reassuring reports on the safety of ART, there have been a small number of recent reports suggesting that ART children may be at increased risk for rare congenital malformation syndromes that are related to defects in genome imprinting (Cox *et al*., 2002; DeBaun *et al*., 2003; Halliday *et al*., 2004; Horsthemke *et al*., 2003; Niemitz *et al*., 2004; Olivennes *et al*., 2001; Orstavik *et al*., 2003). At least three children conceived by intracytoplasmic sperm injection (ICSI) have been diagnosed with AS (Horsthemke *et al*., 2003; Orstavik *et al*., 2003) and at least 28 ART children (both in vitro fertilization (IVF) and ICSI cases) have been diagnosed with BWS (Boerrigter *et al*., 2002; Bonduelle *et al*., 2002; DeBaun *et al*., 2003; Gicquel *et al*., 2003; Halliday *et al*., 2004; Koudstaal *et al*., 2000; Maher *et al*., 2003; Olivennes *et al*., 2001; Sutcliffe *et al*., 1995). Because both AS and BWS are rare disorders (each affects approximately 1 in 15 000 children (Nicholls *et al*., 1998)), the appearance of even small numbers of cases is unexpected except among a large sample of births. Therefore, the current data strongly suggests that there is an association between increased risk for AS and BWS and ART. With respect to BWS, the number of affected individuals observed is estimated to be up to nine times the expected incidence (Halliday *et al*., 2004).

The epidemiological assessment that ART may lead to an increase in the frequency of defective genome imprints is also supported by biochemical characterization of alleles at the relevant disease loci. All three cases of AS show allelic DNA methylation patterns characteristic of a sporadic imprinting defect at the AS locus (i.e., complete or mosaic absence of methylation on both maternal and paternal alleles (Horsthemke *et al*., 2003; Orstavik *et al*., 2003)). None of the patients has a cytogenetically visible alteration of chromosome 15 (which occurs in 70% of all AS cases (Nicholls *et al*., 1998)) and none has a detectable microdeletion at the imprinting center, suggesting that all three cases are due to sporadic, primary, epigenetic defects rather than genetic changes. Given that such imprinting defects account for less than 5% of all AS cases (Buiting *et al*., 2001, 2003; Nicholls *et al*., 1998), there is at least a suspicion that all three cases occurring in patients following ICSI are of this type.

The case for the presence of primary epigenetic defects in the majority of the BWS patients found among ART children is also supported by molecular analyses of alleles at the BWS locus on chromosome 11. Nineteen of the 24 patients have been analyzed for "loss of imprinting" ("LOI"; defined, in this context, as transcription of both maternal and paternal alleles; or the specific changes in DNA methylation that track with this phenomenon and provide a more robust marker in clinical samples) at one or more imprinted genes within the BWS locus and 13 of the 19 cases showed LOI at either *KCNQ1OT1* (DeBaun *et al*., 2003; Gicquel

et al., 2003; Maher *et al*., 2003) or *H19/IGF2* (DeBaun *et al*., 2003). With the addition of the BWS patients described by Halliday *et al*., 2004, 16 out of a total of 22 cases examined showed LOI. Although imprinting defects are more common in BWS than in AS, LOI still appears to be overrepresented among BWS cases in ART children and ART is, in turn, overrepresented among BWS cases.

4.3. Epigenetic variation diversity

During the last several years, there has been a dramatic increase in the number of studies attempting to elucidate the patterns and interrelationship between DNA methylation, histone modifications, noncoding RNAs, binding of nonhistone chromatin proteins, nuclear positioning and interactions, and so on, which are part of the "epigenetic code" (Article 27, **The histone code and epigenetic inheritance**, Volume 1). Alterations of the chromatin configuration can affect interactions between DNA regions, between chromosomes, and with other molecules. Most of the studies in epigenetic variation have been focused on the different mechanisms and effects on gene expression and its phenotypic consequences, including allelic differences and disease, enhancers and insulators, trans-sensing and paramutation, long-range interactions and nuclear colocation, and so on. However, epigenetic changes have also been found to affect many other chromosomal functions (see the following text). A classical example is the centromere, in which multiple chromatin modifications and proteins play a major role in binding to the poles of the spindle and promoting chromosome segregation. Interestingly, epigenetic changes can generate new domains with similar properties (neocentromeres) that affect the segregation of chromosomes during mitosis and meiosis (Pardo-Manuel de Villena and Sapienza, 2001; Rhoades and Dempsey, 1966; Warburton, 2004). Consequently, changes in the segregation of chromosomes or chromatids can favor the transmission of particular alleles to the next generations, with important consequences in evolution and disease (Pardo-Manuel de Villena and Sapienza, 2001).

Another example of a biochemical process for which there is a strong epigenetic effect is asynchronous DNA replication. Asynchronous replication is characteristic of regions containing monoallelically expressed genes (Mostoslavsky *et al*., 2001; Simon *et al*., 1999) and, therefore, epigenetic differences seem to be the basis for the differential replication between homologs at such regions. Consequently, these chromosomal regions are interesting examples of how epigenetic modifications of chromosomal regions have not one but multiple effects (on replication and expression). In addition, a recent survey of asynchronously replicated regions have found that they are located in close proximity to areas of tandem gene duplication (Gimelbrant and Chess, 2006) – although whether such epigenetic marks play a role in chromosome stability in regions of duplications remains to be determined.

Meiotic pairing and recombination constitute another example of a cellular process in which epigenetic marking appears to play an important role. Functional and epigenetic differences between paternal and maternal chromosomes are a common observation in sexually reproducing organisms (reviewed in de la Casa-Esperon and Sapienza, 2003; Pardo-Manuel de Villena *et al*., 2000). However, only

a few of such differences have been associated with imprinted gene expression. Consequently, it has been postulated that parent-of-origin epigenetic differences share a common origin and function in all sexually reproducing organisms: to allow the recognition (and distinction) between homologous chromosomes during the processes of recombination and repair (de la Casa-Esperon and Sapienza, 2003; Pardo-Manuel de Villena *et al*., 2000). Indeed, a recent study has shown that DNA methylation has a role in early meiotic stages: mice deficient in the DNA methyltransferase 3-like (*Dnmt3L*) gene are sterile and display abnormal chromosome synapsis during meiosis (Bourc'his and Bestor, 2004). Curiously, normal expression of *Dnmt3L* occurs not in the meiotic cells, but in their precursors. Hence, the epigenetic signals must be inherited through multiple cell divisions. Such epigenetic signals are observed as DNA methylation of retrotransposons, which appear demethylated in *Dnmt3L* knockout male germ cells. While methylation participates in the normal silencing of mobile elements, retrotransposons are transcribed in the mutant mice. Therefore, *Dnmt3L* mutant mice represent an example of how epigenetic changes can not only affect transcription but can also reshape the genome by affecting synapsis and allowing the mobilization of retrotransposons into new locations, with multiple consequences. Consequently, studies of epigenetic variation cannot be restricted to effects on gene expression, because it can also modulate many other chromosome functions (de la Casa-Esperon and Sapienza, 2003; Pardo-Manuel de Villena *et al*., 2000; Sandovici *et al*., 2005).

5. Conclusions

When discussing epigenetic variation, it is important to remember that we know little about either the underlying mechanisms or the consequences. To mention a few recent examples, studies on the viable yellow allele of the mouse agouti locus (A^{vy}) have shown that the expression of the agouti gene is correlated with the methylation status of upstream sequences (Article 36, **Variable expressivity and epigenetics**, Volume 1). Interestingly, epigenetic inheritance at this locus is not due to such methylation marks, because they are erased during embryonic development (Blewitt *et al*., 2006). Therefore, other epigenetic marks are responsible for the transmission of this epiallele to the offspring. In this review, although we have mostly mentioned examples of variability in methylation (because it has been the most frequently studied epigenetic mark in mammals and is the first subject of the Human Epigenome Project (Eckhardt *et al*., 2004)), we hope that current and future studies will bring to light epigenetic variation at many other levels. For instance, studies of the effects of histone tail modifications at multiple amino acid residues are an expanding field, because the spectrum of modifications and residues affected continues to grow (Article 27, **The histone code and epigenetic inheritance**, Volume 1). In addition, new epigenetic marks and inheritance modes are likely to be discovered. For instance, the role of small RNAs on epigenetic changes has become prominent since the discovery of RNA interference in *Caenorhabditis elegans* (Fire *et al*., 1998). Recent studies have revealed striking new roles for RNA in non-Mendelian epigenetic inheritance, similar to paramutation in plants.

The homozygous wild-type progeny of mice that are heterozygous for a mutation in the *Kit* gene (Rassoulzadegan *et al*., 2006) are found to exhibit the white spotting phenotype that is characteristic of mice that carry a *Kit* mutation. Elaboration of this phenotype is related to the zygotic inheritance of abnormally processed RNAs of the normal allele.

A realistic description of the scale of epigenetic variation is hampered by the diversity of causes and consequences and because the mechanism by which many epigenetic marks are heritable remains obscure. An increasing number of studies are aiming to integrate profiles from different epigenetic marks and gene expression patterns of particular chromosomal regions, in order to better understand the possibilities of variations on the epigenetic code. The complexity and diversity of the epigenetic marks and their implications poses a tremendous challenge, but understanding the nature of the immense phenotypic diversity that surrounds us makes it worth the effort.

Specialist Review

How to get extra performance from a chromosome: recognition and modification of the X chromosome in male *Drosophila melanogaster*

Ying Kong and **Victoria H. Meller**
Wayne State University, Detroit, US

1. Differentiated sex chromosomes cause genetic imbalance

Many organisms have a single X chromosome in males and two in females. The X chromosome is gene-rich and carries genes required in both sexes. By contrast, the Y is often gene-poor, and may carry genes only required in males. The resulting imbalance in the dosage of X-linked genes is fatal if not addressed early in life. Equalization of expression between the sexes is an essential feature of differentiation in flies, mammals, and the worm *Caenorhabditis elegans*. Although the problem is common, the strategy used to solve it in each of these organisms is distinct (Figure 1). To equalize expression between *C. elegans* males (XO; one X chromosome but no Y chromosome) and XX hermaphrodites, hermaphrodites reduce transcription from both X chromosomes by 50%. Mammalian females silence most genes on a single X chromosome. The remaining X chromosome is transcriptionally equivalent to the single X chromosome of males. By contrast, *Drosophila* males increase expression from their single X chromosome about twofold. Although these methods for equalizing expression are overtly very different, each organism regulates the X chromosome through modulation of chromatin architecture.

These animals must accurately and selectively modulate a single chromosome or a pair of chromosomes in one sex. Interestingly, both mammals and flies use large noncoding RNAs to direct chromatin-modifying proteins that regulate expression. The large *Xist* (*X inactive specific transcript*) is transcribed from and directs silencing to the inactive X chromosome of mammalian females (reviewed by Plath *et al*., 2002). As silencing of both X chromosomes would be lethal, this process is restricted to chromatin *in cis* to a single *Xist* allele. *Drosophila* males have two large, noncoding transcripts, *roX1* (*RNA on the X1*), and *roX2* (*RNA on the X2*), that are necessary for localization of a complex of proteins and *roX* RNA to the male X chromosome (Meller and Rattner, 2002). In both mammals and flies, this process likely involves two steps: recruitment of a protein complex,

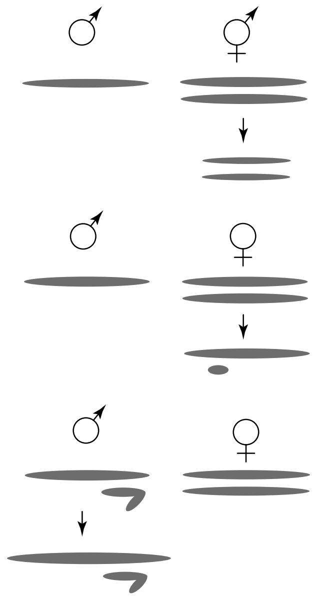

Figure 1 Organisms use divergent strategies to compensate sex chromosome gene dosage. (a) *C. elegans* hermaphrodites (right) have 2 X chromosomes, whereas males have a single X chromosome and no Y chromosome (left). Association of the repressive DCC complex reduces expression of both hermaphrodite X chromosomes by about 50%. (b) Mammalian females (right) randomly silence a single X chromosome. The remaining active X chromosome is transcriptionally equivalent to the single X chromosome of males. (c) *Drosophila* males increase expression from their X chromosome by modulation of chromatin structure (left). Female X chromosomes remain unchanged

followed by modulation of gene expression. This review will focus on advances in understanding the process of recognition and modulation in flies. It will center on the role of the *roX* transcripts in recognition and modification of the X chromosome.

2. RNA and protein coat the X chromosome of *Drosophila* males

Many of the genes necessary for dosage compensation in flies were identified through male-specific lethal (*msl*) mutations. These genes, *maleless* (*mle*), the *male-specific lethals 1*, *-2*, and *-3* (*msl1*, *-2*, and *-3*), and *males absent on first* (*mof*), are collectively known as the *male-specific lethals* (recently reviewed by Mendjan and Akhtar, 2007). Mutations in these genes cause developmental delay and lethality in males, but none is essential in females. The genes that encode the *roX* RNAs are X linked and functionally redundant for dosage compensation. Both properties make them unlikely to be identified by conventional mutagenesis and phenotypic analysis. Accordingly, the *roX* genes were discovered serendipitously (Amrein and Axel, 1997; Meller *et al*., 1997). Immunolocalization of MSL proteins or *in situ* hybridization to *roX* on polytene preparations reveals finely banded

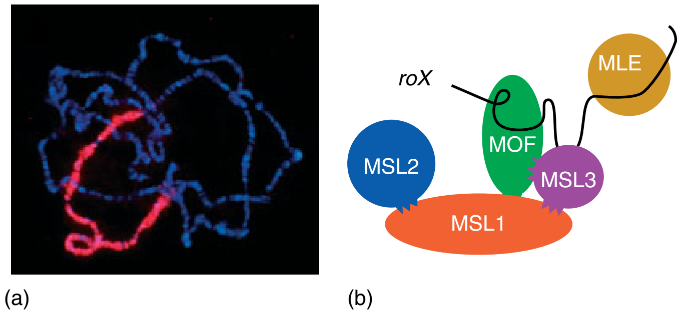

Figure 2 MSL proteins and *roX* RNA form a complex that binds to the *Drosophila* X chromosome. (a) Immunodetection of MSL2 on a polytene chromosome preparation from a male larva. The X chromosome binds MSL2, MSL3 detected with Texas Red. DNA appears blue. (b) Molecular interactions between MSL proteins and RNA. Interactions between proteins are denoted by teeth. Potential interactions are modeled between a single *roX* transcript (black line) and proteins reported to have RNA-binding activity. Protein/protein and protein/RNA interactions are reported by Akhtar *et al*. (2000); Buscaino *et al*. (2003); Copps *et al*. (1998); Li *et al*. (2005); Morales *et al*. (2004); Scott *et al*. (2000)

enrichment along the X chromosome (Figure 2). The MSL proteins and *roX* RNA coimmunoprecipitate, demonstrating that they form a complex (Meller *et al*., 2000; Smith *et al*., 2000). Removal of individual members of the complex disrupts its localization and can reduce the stability of remaining molecules. This is particularly dramatic for the *roX* RNAs, which are unstable upon elimination of any MSL protein (Meller *et al*., 1997; Amrein and Axel, 1997). Mutation of *mle*, *msl3*, or *mof* reduces X-chromosome binding by remaining members of the complex, but a subset of sites able to bind the remaining proteins is retained on the X chromosome. The most prominent of these sites are the *roX* genes themselves (reviewed by Kelley, 2004). MSL1 and MSL2 have a more central role in regulation and assembly of the MSL complex as elimination of either of these proteins prevents all chromatin binding by remaining complex members (Lyman *et al*., 1997). In contrast, simultaneous elimination of both *roX* RNAs shifts the MSL proteins from the X chromosome to ectopic autosomal sites and results in reduced X-linked gene expression (Deng and Meller, 2006; Deng *et al*., 2005; Meller and Rattner, 2002). Recognition of the X chromosome is thus a property of the intact MSL complex, and is not attributable solely to a single participating molecule.

3. Proteins associated with the MSL complex modify chromatin

Increased expression of the male X chromosome is believed to result from changes in chromatin architecture induced by MSL complex. One member of the MSL complex, MOF, is an acetyltransferase specific for lysine 16 of H4 (Akhtar and Becker, 2000; Hilfiker *et al*., 1997; Smith *et al*., 2000). This modification is generally associated with active chromatin, and is highly enriched on the male X chromosome of flies (Turner *et al*., 1992). Acetylation of H4K16 by MOF

increases transcription *in vitro* and *in vivo* (Akhtar and Becker, 2000). Effector proteins that mediate transcriptional change bind to some modified histones, but none specific for H4K16Ac has been found. A recent study demonstrated that acetylation of H4K16 inhibits the formation of highly compact chromatin by disrupting charge-based internucleosomal interactions (Shogren-Knaak *et al*., 2006). This structural effect partially decondenses chromatin, thereby increasing the accessibility of the DNA template. In humans, H4acK16 is found uiquitously on all chromosomes except for the inactive X chromosome (Jeppesen and Turner, 1993). In flies, H4AcK16 colocalizes with the MSL complex (Bone *et al*., 1994; Turner *et al*., 1992).

A second modification linked to increased expression, phosphorylation of H3 on serine 10 (H3pS10), is also enriched on the male X chromosome (Jin *et al*., 1999; Mahadevan *et al*., 2004). H3pS10 in interphase cells is directed by the JIL-1 kinase (Wang *et al*., 2001). Proper dosage compensation of the X-linked *white* gene requires JIL-1 function (Lerach *et al*., 2005). In addition to compensation of the male X chromosome, JIL-1 has a general role in maintenance of chromatin structure and limits the spread of heterochromatin into euchromatic regions (Zhang *et al*., 2005). Accordingly, JIL-1 is an essential gene required in both sexes (Wang *et al*., 2001). The male X chromosome is therefore marked with at least two histone modifications that are associated with elevated transcription and decreased chromatin condensation. It is likely that the primary function of the MSL complex is to direct and control these modifications.

4. The MSL complex increases transcription by a general method

X chromosome compensation affects hundreds of genes with different expression levels and profiles. It must therefore be superimposed on genes with distinct regulatory strategies. Interestingly, chromatin immuno and affinity precipitation of DNA bound by the MSL complex detects modest levels of these proteins in promoter regions, but higher levels within the body of most actively transcribed genes (Alekseyenko *et al*., 2006; Gilfillan *et al*., 2006; Legube *et al*., 2006). H4Ac16 has also been found to be high in the body of X-linked genes (Smith *et al*., 2001). Reduced chromatin compaction may increase the speed or processivity of RNA polymerase. Enhanced expression is thus likely to result from facilitation of transcriptional elongation, rather than increased initiation (Henikoff and Meneely, 1993). Alternatively, modifications at the 3′ end of transcription units may enhance reinitiation by recycled RNA polymerase (Dieci and Sentenac, 2003).

A second theory of how the MSL complex enhances expression stems from a recent study that identified nuclear pore components copurifying with tagged MOF and MSL3 (Mendjan *et al*., 2006). This study found no classical transcriptional factors but identified exosome components and interband binding proteins in association with MSL proteins. Knock down of the nuclear pore proteins Mtor and Nup153 disrupted the location of MSL proteins and compensation of some X-linked genes, suggesting that interaction with the nuclear pore is important for

localization of the MSL complex (Mendjan *et al*., 2006). An association with the nuclear pore might facilitate transcriptional elongation by affecting RNA processing and transportation. The nuclear pore might alternatively establish a transcriptionally active compartment or a region of facilitated chromatin remodeling within the nucleus (Casolari *et al*., 2005; Feuerbach *et al*., 2002). Tethering transcription units to nuclear pores facilitates expression in yeast, supporting the involvement of this structure in activation (Cabal *et al*., 2006; Taddei *et al*., 2006). Recruitment of silenced genes into a repressive nuclear compartment has been proposed as the mechanism of X-chromosome inactivation in mammals. The inactive X chromosome (X_i) occupies a region adjacent to the nucleolus during replication (Zhang *et al*., 2007). This may ensure epigenetic maintenance of the silent state through replication. X-linked gene inactivation is accompanied by movement of individual genes from the outer fringe of the domain occupied by the X_i to a more interior position from which RNA polymerase is excluded (Chaumeil *et al*., 2006). Thus X inactivation and its perpetuation may rely on recruitment of genes and the X chromosome into specific nuclear compartments. It is unknown if dosage compensation in flies involves repositioning of genes into transcriptionally active domains. However, this method is appealing as it is well adapted to control closely linked genes and could do so by a general method that is superimposed on genes with different regulatory strategies.

5. Large RNAs that control X chromosomes: powerful but mysterious molecules

Regulatory RNAs that coat the X chromosome play a key role in dosage compensation in mammals and *Drosophila*. In spite of the central role of *roX* transcripts in fly dosage compensation, how they interact with the MSL proteins, and how this changes the properties of the MSL complex, remains speculative. A comparison with *Xist* may prove valuable. *Xist* is well studied and shares unusual properties with the *roX* RNAs. Both RNAs coat the dosage-compensated X chromosomes, direct protein complexes to chromatin, and are able to recruit chromatin-modifying activities *in cis* to the site of RNA synthesis.

Xist is transcribed from the *Xic* (*X inactivation center*) and is essential for initiation and propagation of X-chromosome inactivation (reviewed by Plath *et al*., 2002). *Xist* is selectively expressed from one X chromosome and spreads *in cis* from the site of synthesis to coat most of this chromosome. *Xist* recruits polycomb proteins that introduce repressive histone modifications (Plath *et al*., 2004; Silva *et al*., 2003). Several days after the initiation of X inactivation, the inactivation becomes largely independent of *Xist*. Additional changes in chromatin, such as enrichment for variant histones and methylation of CpG islands, characterize the differentiated X_i (reviewed by Lucchesi *et al*., 2005). Distinct sequences within *Xist* are responsible for localization to the X chromosome and for silencing (Figure 3a; Wutz *et al*., 2002). Several widely separated *Xist* sequences act cooperatively to direct X localization, and a repeated element that folds into shortstem loops mediates silencing as well as localization (Wutz *et al*., 2002).

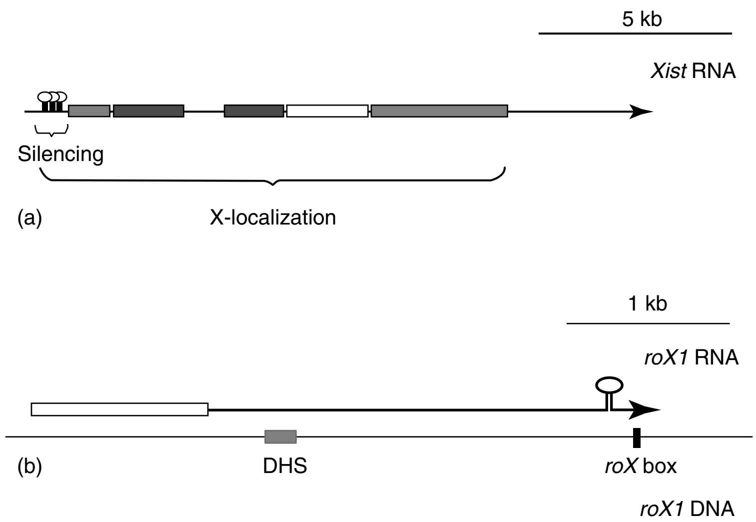

Figure 3 *roX1* and *Xist* have distinct regions necessary for gene function. (a) The *Xist* transcript has a series of 15 shortstem loops near the 5′ end that are necessary for silencing. Distributed elements that contribute to X localization are shown as gray and white boxes. The strongest of these are darkest. Figure is based on (Wutz, 2003; Wutz *et al*., 2002). (b) Functional and conserved regions of *roX1* RNA (top) and DNA (bottom) are represented. One kb at the 5′ end of *roX1* (open box on left) is necessary for wild-type localization of the MSL complex. Between this and the 3′ stem loop (right) there is no identified element necessary for RNA function. The 200 bp *roX1* DNase hypersensitive site (DHS) is shown as a gray box on the *roX1* DNA. This sequence attracts the MSL complex. The 30 bp "*roX* box" (black) is at the right. This is based on (Kageyama *et al*., 2001; Park *et al*., 2003; Stuckenholz *et al*., 2003)

This repeat is also necessary for relocalization of silenced genes inside the domain occupied by the X_i (Chaumeil *et al*., 2006).

roX1 also has multiple regions necessary for function (Figure 3b). In spite of being redundant, the *roX* transcripts share little similarity that can be used to identify potentially important sequences (Amrein and Axel, 1997; Park *et al*., 2003). A highly conserved 30 bp "*roX* box" is present at the 3′ end of both *roX* RNAs (Franke and Baker, 1999). This region is dispensable for function (Stuckenholz *et al*., 2003). A weakly conserved 200 bp sequence within each *roX* gene strongly attracts the MSL proteins and forms a male-specific DNaseI hypersensitive site (Kageyama *et al*., 2001; Park *et al*., 2003). The *roX1* DNase hypersensitive site (DHS) acts as an enhancer of *roX1* transcription in males and a repressor in females (Bai *et al*., 2004). However, internal deletions of *roX1* lacking the DHS are still regulated in a sex-specific manner, and *roX1* alleles and transgenes lacking this sequence retain full activity (Deng *et al*., 2005; Rattner and Meller, 2004; Stuckenholz *et al*., 2003). Although the role of the DHS remains speculative, all evidence points to its function as DNA, rather than RNA. Two *roX1* regions necessary for transcript activity have been identified. A stem loop close to the 3′ end is the only structural feature linked to *roX1* function (Stuckenholz *et al*., 2003). Transgenes deleted for the stem loop or with disrupted pairing of the stem have low rescue of *roX1*$^-$ *roX2*$^-$ males in spite of substantial recruitment of MSL

proteins to the X chromosome. It is possible that this sequence influences chromatin modification or gene activation by the MSL complex. Deletion of 1 kb at the 5′ end of *roX1* also destroys activity. When large portions of this region are removed by internal deletion, *roX1* activity is reduced commensurate with the amount deleted (Deng *et al*., 2005). Small (∼300 bp) deletions scanning the 5′ end have failed to identify discrete elements, suggesting redundancy (Stuckenholz *et al*., 2003). Males that carry a *roX1* allele with a large part of the 5′ end missing display ectopic MSL binding and reduced coverage of the X chromosome, suggesting that this region is necessary for recognition of the X chromosome (Deng *et al*., 2005). An internal deletion of 2.4 kb that retains 0.8 kb of 5′ end and 0.6 kb of the 3′ end, including the stem loop, supports full male survival (Deng *et al*., 2005). However, simultaneous expression of separate 3′ and 5′ fragments of *roX1* does not rescue either MSL localization or male survival (Meller and Rattner, 2002; Stuckenholz *et al*., 2003). Taken together, these observations suggest that *roX* activity requires simultaneous interaction with different molecules. An attractive model is that *roX1*, like *Xist*, has distinct domains necessary for X chromosome localization and gene activation.

The major *roX2* splice form is 600 bp, and functional domains within this molecule remain to be identified. A multitude of alternative *roX2* splice forms with decreased activity has been found (Park *et al*., 2005). *roX2* molecules with different levels of activity may modulate the activity of the MSL complex, thus fine-tuning the level of X chromosome activation.

6. MSL proteins have RNA-binding activity

MLE is an RNA/DNA helicase with higher activity on RNA substrates (Lee *et al*., 1997). The helicase activity of MLE is essential for normal localization of the MSL complex on the X chromosome and for movement of the *roX* RNAs from their sites of synthesis, suggesting a role in integration of *roX* into the mature MSL complex (Gu *et al*., 2000; Meller *et al*., 2000). MLE itself does not interact with other MSL proteins and can only be coimmunoprecipitated under nonstringent conditions using antibodies that pull down other MSL proteins (Smith *et al*., 2000). MLE can be released from polytene chromosomes by RNase A digestion, suggesting that it associates with the MSL complex through an RNA (Figure 2b; Richter *et al*., 1996). The stability of *roX1* is particularly dependent on MLE, supporting the idea of a direct interaction between these molecules (Meller, 2003).

Both MSL3 and MOF have RNA-binding activity *in vitro* and their localization on the X chromosome is destabilized by RNase digestion (Akhtar *et al*., 2000; Buscaino *et al*., 2003). Both proteins have variant chromo domains that have been implicated in RNA binding. Whereas the canonical chromo domains of Heterochromatin protein 1 (HP1) and Polycomb (Pc) bind methylated histones by aromatic residues, the variant structures found in MOF and MSL3, named *chromo barrel domains*, may have different functions (Lachner *et al*., 2001; Bannister *et al*., 2001). The MOF chromo barrel lacks aromatic residues that recognize methylated peptides (Nielsen *et al*., 2005). This region contributes to MOF’s ability to bind RNA *in vitro* (Akhtar *et al*., 2000). The chromo barrel of MSL3 has also been implicated in RNA binding, but retains the aromatic residues necessary for

methyl group binding (Nielsen *et al*., 2005). Mutation of the MSL3 chromo barrel prevents increased transcription of X-linked genes, but does not affect targeting of the complex to the X chromosome (Buscaino *et al*., 2006). Deletion of a different domain of MSL3 blocks X chromosome localization, reinforcing the idea that MSL complex localization and gene activation are separable.

These studies suggest that multiple RNA/protein contacts within the MSL complex might fine-tune the activity of the complex. The H4 acetyltransferase activity of MOF is greatly increased by association with MSL1 and MSL3, suggesting a mechanism for limiting MOF activity until it assembles with a regulatory complex (Morales *et al*., 2004). MSL1, -2, -3, and MOF continue to associate in the absence of *roX*, but only low levels of H4Ac16 are detected at sites bound by these proteins (Deng and Meller, 2006). This may reflect a reduced MOF activity in the absence of *roX* RNA.

7. Do *roX* and MLE recruit a preexisting chromatin-binding complex?

The discovery that the yeast NuA4 transcriptional regulator contains subunits similar to MSL3 and MOF Esa/p-associated factor (Eaf3p and Esa1p) and characterization of a mammalian complex containing MSL homologs suggests that the association of these proteins is ancient (Eisen *et al*., 2001; Marin and Baker, 2000; Smith *et al*., 2005; Taipale *et al*., 2005). Human MOF (hMOF) participates in multiple protein assemblies and is required for normal function of human ATM (ataxia-telangiectasia-mutated) protein in DNA repair (Gupta *et al*., 2005; Taipale *et al*., 2005).

roX RNAs have only been identified in closely related Drosophilids, but helicases with similarity to MLE have been identified from yeast to mammals (Park *et al*., 2003; Sanjuan and Marin, 2001). MLE homologs have not yet been isolated in complexes of MSL-like proteins outside of flies. MLE has a peripheral association with the fly MSL complex, and is presumably tethered by RNA. It thus seems plausible that the addition of MLE to the MSL complex depends on the presence of *roX*. The importance of *roX* in correct targeting of the MSL complex suggests that the addition of noncoding RNA was a major step in recruitment for the purpose of X chromosome compensation.

8. Recognition of X chromosomes

A mechanism that targets changes in expression to a single chromosome is a fundamental requirement of dosage compensation. Two distinct strategies for accomplishing this have been described. The chromosome may be controlled by spread of regulation from *cis*-acting elements. The *Xic* is a strong *cis*-acting element capable of directing silencing to an entire X chromosome (Figure 4a). It can also silence autosomal chromatin if *Xist* is inserted on the autosome. *Xist* RNA produced from the *Xic* does not work *in trans*, thus protecting one X chromosome from inactivation. An alternative mechanism for distinguishing a chromosome is finely dispersed

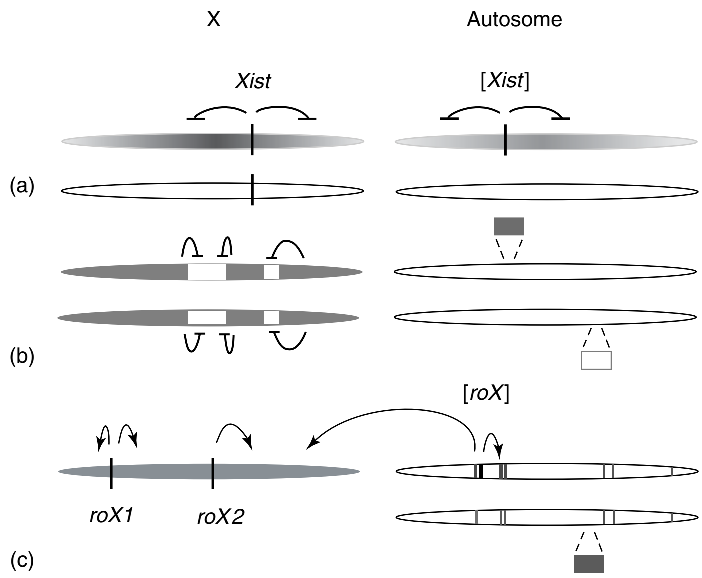

Figure 4 Strategies for X chromosome recognition in mammals, flies and worms. (a) One of two *X inactivation centers* present in females produces *Xist* RNA (top left). The chromosome carrying this allele becomes the inactive X (shaded). A transgene carrying *Xist* can silence autosomal chromatin *in cis* (shaded, right). (b) The *C. elegans* X chromosome is distinguished by sequence elements (gray shading). The distribution of these elements is uneven, leaving large gaps (white). The repressive DCC spreads into these gaps from flanking regions. Segments separated from the rest of the X chromosome attract the DCC if they have X-recognition sequences (autosomal insertion, top) but remain uncompensated if they lack these elements (autosomal insertion, bottom). (c) The *Drosophila* X chromosome is finely marked by sequences that attract the MSL complex (gray). Translocated X chromosome fragments are recognized accurately (autosomal insertion, bottom). Weak and scattered MSL-binding sites on the autosomes do not attract the MSL complex in normal males (gray lines, right). *roX1* and *roX2* (vertical black lines) produce *roX* RNA and are *cis*-acting elements that enhance recognition of the X chromosome. A *roX* transgene (top right) enables MSL binding to closely linked autosomal sites. The *roX* transgene also produces transcript that acts *in trans* to compensate an X chromosome

sequence elements. Two short sequences that participate in recognition of the *C. elegans* X chromosome have been identified (McDonel *et al*., 2006). Interestingly, these are not exclusive to the X but cooccur near one another on the X chromosome. This suggests that cooperativity between multiple DNA-binding molecules underlies recognition X chromatin in worms. However, large regions of the *C. elegans* X chromosome fail to bind the repressive dosage compensation complex (DCC) when separated from the X chromosome, but are coated by it when on the X chromosome (Figure 4b) (Csankovszki *et al*., 2004). This indicates that the ability of the DCC to spread *in cis* is necessary for a complete coverage of the *C. elegans* X chromosome.

Translocated segments of the *Drosophila* X chromosome are faithfully recognized by the MSL complex, indicating the presence of finely distributed sequences marking this chromosome (Figure 4c; Fagegaltier and Baker, 2004; Oh *et al*., 2004). Autosomal *roX* transgenes can fully rescue male viability, indicating that *roX* RNA can act *in trans* to its site of synthesis. But under

some conditions, autosomal *roX* insertions also direct MSL binding to chromatin flanking the insertion site (Kelley *et al*., 1999; Park *et al*., 2002). Regional spreading of chromatin modification from the *roX* genes can also be observed on the X chromosome (Bai *et al*., 2007; Oh *et al*., 2003). It therefore appears that recognition of the *Drosophila* X chromosome involves strong, *cis*-acting elements as well as sequences identifying the X chromosome.

Subdivision of DNA clones that recruit the MSL complex and a functional assay for MSL recruitment have identified short sequences that contribute to MSL binding (Dahlsveen *et al*., 2006; Gilfillan *et al*., 2007; Oh *et al*., 2004). These sequences are divergent and display a wide range in affinity for the MSL proteins. Overexpression of MSL proteins also identifies autosomal sites that can recruit the MSL complex, indicating that potential binding sites are not limited to the X chromosome (Demakova *et al*., 2003). An attractive hypothesis is that a dense distribution of strong and weak recruitment sites act cooperatively to mark the X chromosome (Dahlsveen *et al*., 2006; Demakova *et al*., 2003; Fagegaltier and Baker, 2004). Local elevation of the MSL complex by strong sites will enable weaker ones to be bound. The DHS within the *roX1* and *roX2* genes are extraordinarily strong MSL recruitment sites (Kageyama *et al*., 2001). Their ability to induce binding of the MSL complex in autosomal chromatin flanking transgene insertions likely results from enhancement of weak autosomal binding sites (Dahlsveen *et al*., 2006; Kelley *et al*., 1999). Although not absolutely essential for compensation, the situation of the *roX* DHS on the X chromosome will enhance recognition of the X.

X-chromosome binding of the MSL proteins is disrupted in *roX1*$^{-}$*roX2*$^{-}$ males, but these proteins continue to colocalize at ectopic autosomal sites. The *roX* transcripts are therefore not essential for chromatin binding, but ensure high selectivity of the intact MSL complex for the X chromosome. Assembly with *roX* might enhance the ability of the MSL complex to recognize *cis*-acting elements on the X chromosome. Alternatively, the resulting change in the complex could promote cooperative binding to closely situated sites. This would favor the X chromosome, proposed to have dense mix of strong and weak sites, over the autosomes, which have more scattered sites capable of recruiting MSL proteins (Demakova *et al*., 2003).

The distribution pattern of the MSL complex in the body of genes suggests that localization is largely established by transcriptional activity (Alekseyenko *et al*., 2006; Gilfillan *et al*., 2006; Legube *et al*., 2006). This could occur by association with the transcription machinery or interaction with nascent transcripts. Alternatively, the MSL complex could be targeted to modified histones in the wake of a transcribing polymerase. These methods would identify transcribed regions, but are unable to distinguish between X-linked and autosomal genes. Closely linked genes will be transcribed in proximity to one another, and thus may be influenced by their neighbors. Linked mammalian genes often associate at "transcription factories" (Osborne *et al*., 2004). Although there is no evidence for analogous transcription factories in *Drosophila*, identification of proteins from the nuclear pore in association with the MSL complex suggests recruitment to a transcriptionally active region. It is possible that some elements marking the X chromosome direct transcribed genes to regions where MSL loading can occur, rather than interacting directly with the MSL complex itself. This would explain

why sequences necessary for compensation of the *white* gene are found in the promoter as well as within the body of the gene (Qian and Pirrotta, 1995).

9. Concluding remarks

Dosage compensation in *Drosophila* is a remarkable model system for the study of epigenetic regulation. It is also rich in common principles of chromatin-based transcription control. Regulation of the male X chromosome involves histone modifications that are proposed to act by increasing the speed, processivity, or reinitiation rate of RNA polymerase. Similar mechanisms will be relevant for the regulation of all eukaryotic genes. Modification of the *Drosophila* X chromosome is targeted by cues including a favorable density of *cis*-acting DNA elements, transcriptional activity and possibly recruitment to regions where cotranscriptional MSL loading is promoted or transcription is facilitated. Together these produce highly selective recognition and modulation of a single chromosome. Understanding how noncoding RNAs such as *roX* coordinate this process will enhance our understanding of long-range epigenetic processes in all eukaryotes.

Short Specialist Review

DNA methylation in epigenetics, development, and imprinting

Hiroyuki Sasaki
National Institute of Genetics, Mishima, Japan

1. DNA methylation in epigenetics

In the vertebrate genome, over 60% of CpG dinucleotides are methylated at the 5 position of the cytosine residue. The product of this methylation is 5-methylcytosine (5mC), which is the only physiologically modified base seen in the vertebrate genome. 5mC provides additional information to DNA sequences and serves as an excellent epigenetic mark. The idea that 5mC might influence gene expression was first postulated by Holiday and Pugh (1975) and Riggs (1975). As will be discussed below, vertebrates, including mammals, indeed use methylation for developmental and tissue-specific control of gene expression.

The eukaryotic DNA methylation system has its roots in the restriction/modification system of prokaryotes (a defense mechanism against bacteriophages). The catalytic domain of mammalian DNA methyltransferases (DNMTs) shares conserved motifs with prokaryotic cytosine modification enzymes (Bestor *et al*., 1988; Okano *et al*., 1998). Although methylation is present almost universally in eukaryotes, there are exceptions such as yeast (*Saccharomyces cerevisiae*) and nematode (*Caenorhabditis elegans*), which live happily without it. Because these organisms have relatively small genomes, it is proposed that the primary function of methylation is to differentiate active and inactive regions in higher eukaryotes with complex genomes. Silencing of transposons may be another but related primary function of methylation.

A key feature of methylation in vertebrates is that it occurs at CpG dinucleotides. This means that DNA can be methylated symmetrically on both strands (Figure 1). Unmodified CpGs are methylated by de novo methyltransferases DNMT3A and/or DNMT3B (Okano *et al*., 1998), which transfer a methyl group from the methyl donor *S*-adenosylmethionine to the target cytosine. Upon DNA replication, fully methylated CpGs become hemimethylated, a configuration that is the favored targets for maintenance methyltransferase DNMT1 (Bestor *et al*., 1988). DNMT1 faithfully restores the methylation patterns (Figure 1). If DNMT1 is not present, the sites will eventually lose 5mC after cycles of replication (passive demethylation). Although the presence of an active demethylation system has been suggested, its biochemical nature remains elusive.

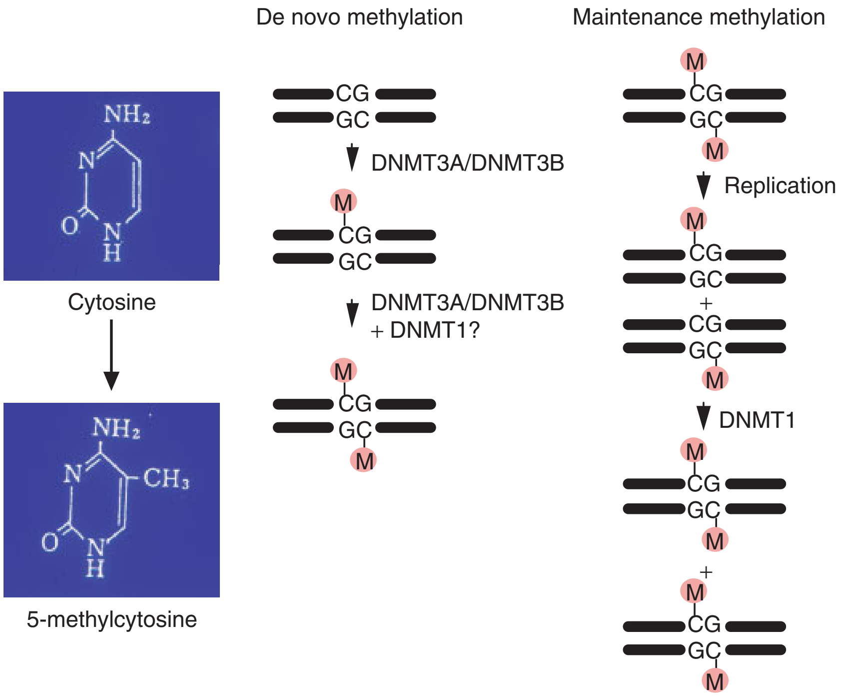

Figure 1 Creation and maintenance of DNA methylation patterns

Because spontaneous deamination of 5mC causes a C to T transition, CpG dinucleotide is underrepresented in the vertebrate genome. However, gene promoters and regulatory regions are often more rich in CpG. These CpGs are the targets for methylation in gene regulation. In particular, approximately half of the genes are associated with small regions (typically 1–2 kb) with a high density of CpG (CpG islands) (Bird, 1986). The CpG islands are normally methylation-free but can be methylated in genomic imprinting (see later) and X-chromosome inactivation (*see* Article 15, **Human X chromosome inactivation**, Volume 1, Article 40, **Spreading of X-chromosome inactivation**, Volume 1, and Article 41, **Initiation of X-chromosome inactivation**, Volume 1).

How does DNA methylation silence genes? Some transcription factors are known to be sensitive to methylation: if 5mC is present in the target sequence, it prevents the factor from binding. However, the number of such factors seems small. Rather, vertebrates evolved a family of methyl-CpG-binding proteins, which share a common methyl-CpG-binding domain (MBD proteins) (Hendrich and Bird, 1998). Binding of MBD proteins to methylated DNA may physically interfere with transcription factor binding. Furthermore, some MBD proteins such as MeCP2 and MBD2 form a multisubunit complex containing histone deacetylases (HDACs) to repress transcription (Nan *et al*., 1998; Jones *et al*., 1998). The complex formed with MBD2 also contains an ATP-dependent chromatin remodeling protein (Wade *et al*., 1999; Zhang *et al*., 1999). Thus, there is interplay between DNA methylation

and chromatin modification/remodeling. Both DNMT1 and DNMT3B also interact with HDACs and can repress transcription (Burgers *et al*., 2002).

2. DNA methylation in development

That DNA methylation plays an essential role in cell differentiation is best illustrated in experiments done with a nucleotide analogue 5-azacytidine (Taylor and Jones, 1979). When a fibroblast cell line was treated with this demethylating agent, various cell types, including fat cells and muscle cells, appeared in the culture dish. This suggested a massive reactivation of genes that are normally silent in fibroblast cells. Consistent with this, it is well established that different cell types have their respective methylation patterns.

How and when are such tissue-specific methylation patterns established? The global methylation level changes dynamically during mammalian development (Figure 2). The sperm- and oocyte-derived genomes first experience massive demethylation in cleavage stage embryos (*see* Article 33, **Epigenetic reprogramming in germ cells and preimplantation embryos**, Volume 1). (However, the paternal and maternal imprints are maintained even in this stage. See later.) This is mainly due to exclusion of DNMT1 from the nucleus, but there is evidence that the sperm-derived genome is actively demethylated soon after fertilization (*see* Article 33, **Epigenetic reprogramming in germ cells and preimplantation**

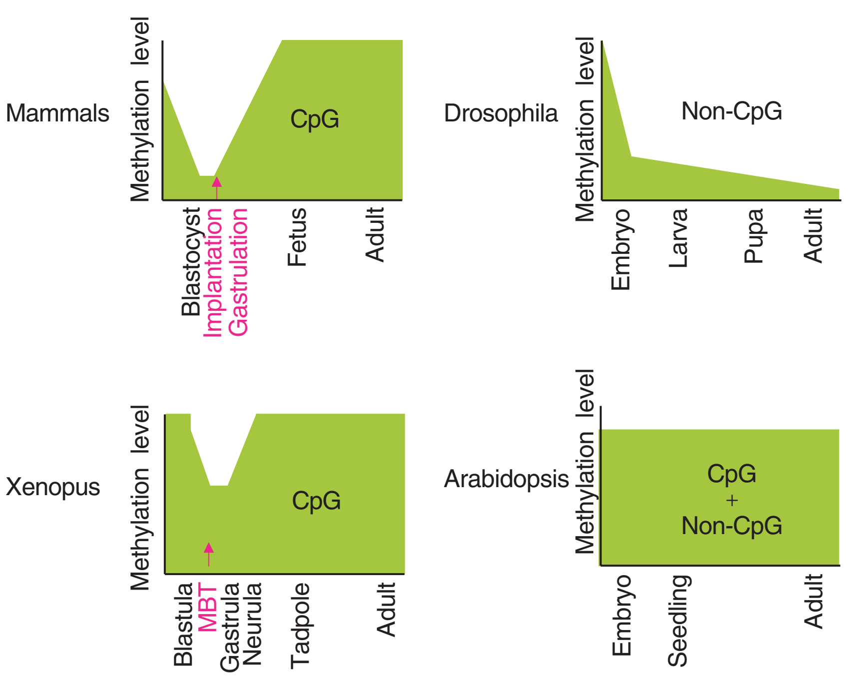

Figure 2 Global changes in DNA methylation during development

embryos, Volume 1). After implantation, DNMT3A and DNMT3B establish methylation patterns specific to individual cell lineages (Okano *et al*., 1999). DNMT1 then maintains the tissue-specific methylation patterns (Li *et al*., 1992). However, extraembryonic tissues and germ cells maintain relatively low methylation levels (*see* Article 33, **Epigenetic reprogramming in germ cells and preimplantation embryos**, Volume 1).

Differentiation-dependent changes in methylation are recapitulated in embryonic stem (ES) cells, which are derived from the inner cell mass of blastocysts. Undifferentiated ES cells have a methylation level lower than that of the somatic tissues but, when they are induced to differentiate, de novo methylation by DNMT3A and DNMT3B occurs. This provides a model to study epigenetic control of developmental gene expression.

Developmental changes in methylation are less well characterized in other organisms, but frogs (*Xenopus laevis*) show demethylation in early embryos toward the mid-blastula transition, just like preimplantation mammalian embryos. In fruit fly (*Drosophila melanogaster*), methylation is seen only during early development. All these dynamic changes suggest that methylation probably has a role in the development of these animals. However, in plants such as *Arabidopsis thaliana*, no global methylation change is seen.

Direct evidence that DNA methylation is crucial for normal development comes from gene knockout studies in mice. A targeted disruption of DNMT1, which removes almost all genomic methylation due to lack of maintenance activity, causes early embryonic death (Li *et al*., 1992). Similarly, mice deficient for DNMT3A die at an early postnatal stage and those deficient for DNMT3B die at a late embryonic stage, respectively (Okano *et al*., 1999). DNMT3A/DNMT3B double mutants die even earlier, similar to the stage at which the DNMT1 mutants die. Interestingly, DNMT3B mutations, but not DNMT3A mutations, cause loss of methylation of pericentromeric minor satellite DNA. Consistent with this observation, DNMT3B mutations cause ICF (immunodeficiency, centromeric instability, facial anomalies) syndrome in humans (Okano *et al*., 1999; Xu *et al*., 1999).

3. DNA methylation in imprinting

Normal mammalian development requires both a paternal and a maternal genome, and thus parthenogenesis is not possible. The functional differences between the paternal and maternal genomes are due to the differential expression of the paternal and maternal alleles of a small subset (up to a few hundred) of genes (*see* Article 45, **Bioinformatics and the identification of imprinted genes in mammals**, Volume 1 and Article 46, **UPD in human and mouse and role in identification of imprinted loci**, Volume 1). For example, *Igf2* is only expressed from the paternal allele, and *H19* is only expressed from the maternal allele in both humans and mice. The differences between the parental alleles originate from the differential epigenetic modification of the genome in the male and female gametes, a phenomenon called *genomic imprinting*. Imprinting is crucial for normal mammalian development and is relevant to congenital malformation syndromes and cancers in humans (*see* Article 26, **Imprinting and epigenetic inheritance in human disease**, Volume 1,

Article 29, **Imprinting in Prader–Willi and Angelman syndromes**, Volume 1, Article 30, **Beckwith–Wiedemann syndrome**, Volume 1, Article 31, **Imprinting at the *GNAS* locus and endocrine disease**, Volume 1, and Article 46, **UPD in human and mouse and role in identification of imprinted loci**, Volume 1).

Imprinted genes tend to form clusters in the genome and are often associated with regions methylated differently on the paternal and maternal alleles. Such regions are called differentially methylated regions (DMRs) and many of them are CpG islands. There are at least two classes of DMRs, one methylated during gametogenesis and the other methylated after fertilization. Germ-line deletion experiments in mice have shown that some DMRs belonging to the former class control multiple imprinted genes of the cluster (imprint control region or imprinting center). The gamete-derived methylation patterns of imprinted genes are maintained in the somatic tissues throughout embryonic development, but are erased in primordial germ cells, consistent with the reversibility of imprinting (Figure 3). These findings suggest that DNA methylation is the epigenetic mark (imprint) that differentiates the paternal and maternal alleles.

A recent study demonstrated that de novo methylation is required for the establishment of imprints in the gametes. A disruption of DNMT3A, but not DNMT3B, in the female germ cells causes loss of methylation at maternally methylated DMRs and loss of monoallelic expression of their associated genes (Kaneda *et al*., 2004a). Also, disruption of DNMT3A in the male germ cells causes loss of methylation at paternally methylated DMRs (Kaneda *et al*., 2004a). Together with the data from other knockout studies, it is thought that DNMT3A cooperates with DNMT3L, a DNMT3-like protein with no methylation activity, to establish the gametic methylation patterns (Figure 3) (Bourc'his *et al*., 2001; Hata *et al*., 2002).

The gamete-derived methylation patterns of DMRs are maintained in the zygote by maintenance methyltransferase DNMT1 (Figure 3). Thus, a deletion of DNMT1

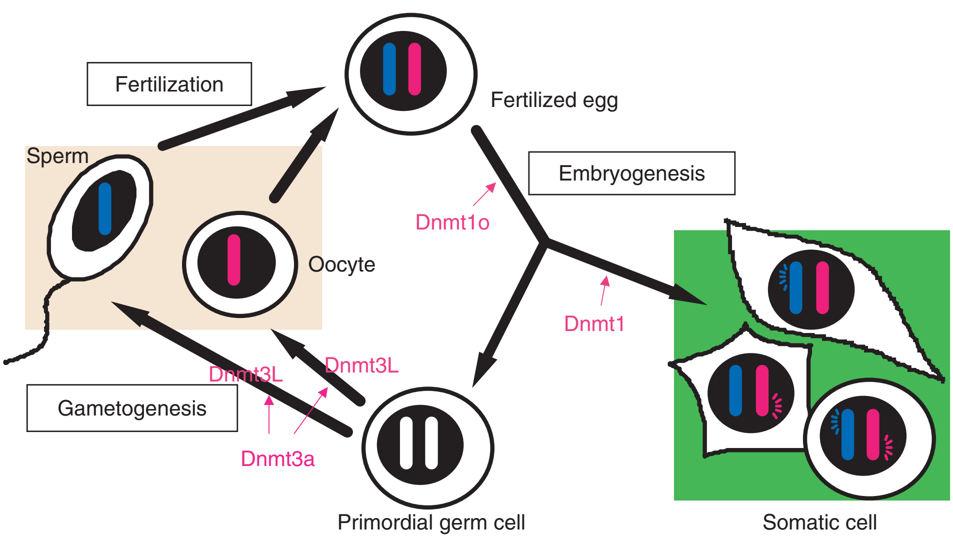

Figure 3 DNA methylation and the cycle of genomic imprinting

causes loss of methylation at both paternally and maternally methylated DMRs and loss of monoallelic expression of all imprinted genes (Li *et al*., 1993; Howell *et al*., 2001). Interestingly, some imprinted genes such as *H19* show reactivation of the normally silent allele but other imprinted genes such as *Igf2* and *Igf2r* show inactivation of the normally active allele (Li *et al*., 1993). This is consistent with the methylation-sensitive insulator model for *Igf2* imprinting and with the antisense regulation model for *Igf2r* imprinting.

Although DNA methylation is the primary mechanism of genomic imprinting, other epigenetic mechanisms are also involved. For example, DMRs show allelic differences in histone modifications (acetylation and methylation) and in accessibility by nucleases. Furthermore, imprinting of a placenta-specific gene *Mash2* has been shown to be tolerant to loss of maintenance methylation. However, even in such cases, the gamete-derived primary imprint is probably DNA methylation (Kaneda *et al*., 2004b).

Genomic imprinting is not unique to mammals, and it also occurs in plants. The *FWA* gene of *Arabidopsis* is only expressed from the maternal allele in the endosperm (a nutritive tissue that can be considered the placental equivalent in plants) (Kinoshita *et al*., 2004). Unlike the mammalian imprinted genes, *FWA* has no gamete-derived imprint. It is methylated in both male and female gametes. In plants, two identical male gametes are delivered by the pollen to two distinct female gametes. A double fertilization process leads to the development of the embryo surrounded by the nurturing endosperm. DNA methylation of *FWA* is maintained throughout embryonic development and plant vegetative phase, but in endosperm, the maternal *FWA* allele become demethylated and expressed (Kinoshita *et al*., 2004). Thus, imprinting of *FWA* does not involve de novo methylation and there is no imprint resetting in germ cells.

Short Specialist Review

Epigenetic reprogramming in germ cells and preimplantation embryos

Abraham L. Kierszenbaum
The Sophie Davis School of Biomedical Education, and The City University of New York Medical School, New York, NY, USA

1. Introduction

Gametogenesis and early embryogenesis in mammals are under the control of genetic and epigenetic mechanisms. A remarkable aspect of epigenetics is the reprogramming of allele-specific gene expression by DNA methylation and histone modifications (acetylation, phosphorylation, methylation, and ubiquitylation). A disruption of these two biochemical events leads to abnormal developmental processes, including Prader–Willi (PWS) and Angelman (AS) syndromes, and the Beckwith–Wiedemann syndrome (*see* Article 29, **Imprinting in Prader–Willi and Angelman syndromes**, Volume 1 and Article 30, **Beckwith–Wiedemann syndrome**, Volume 1) (see Nicholls and Knepper, 2001 for a comprehensive review).

Two clinically related issues are relevant to the epigenetic reprogramming and genomic imprinting in germ cells and preimplantation embryos. First, advances in assisted reproductive technology as an approach to treating infertility have attracted attention to the potential risk of birth defects when major epigenetic events can be disrupted when round spermatids and preimplantation embryo are developed or maintained in culture, respectively (Lucifero *et al*., 2002; Gosden *et al*., 2003). Second, prospects of epigenetic therapy based on inhibitors of enzymes controlling epigenetic modifications, in particular, DNA methyltransferases and histone deacetylases, have opened the possibility that genes that have undergone abnormal epigenetic silencing may be reactivated (Egger *et al*., 2004). This brief review summarizes current knowledge on the developmental occurrence of genomic imprinting during gametogenesis and in the preimplantation embryo. Knowledge of these highly timed events can contribute to implementing safe and efficient assisted reproductive technologies.

2. Components of the epigenetic reprogramming machinery

DNA methylation and histone modifications are epigenetic heritable changes functioning as efficient modulators of transcription. ATP-dependent chromatin

modifications contribute to DNA methylation and histone modification events (see Reik *et al*., 2001; Li, 2002 for comprehensive reviews). DNA methylation occurs at CpG dinucleotides and is catalyzed by DNA methyltransferase 1 (Dnmt1), a maintenance enzyme operating after DNA replication, and Dnmt3a and Dnmt3b, both required for de novo DNA methylation patterns during development. Both Dnmt1 and Dnmt3a interact with histone deacetylases (HDACs) to repress transcription. CpG-binding proteins, with a methyl-CpG-binding domain (MBD), recruit different chromatin-remodeling proteins and transcription regulatory complexes to DNA-methylated regions in the genome. Histone modifications occur at the lysine, arginine, and serine residues located at the amino-terminal tail of histones. Histone methyltransferases include H3-K4 methyltransferase (methylation of lysine 4 of Histone 3; associated with active gene expression), H3-K9 (methylation of lysine 9 of Histone 3; associated with transcriptional silencing), and five H3-K9 methyltransferases (Suv39 h1 and Suv39 h2, G9a, ESET/SetDB1 and Eu-MHTase1). Several HDACs have been identified, including transcription coactivators with intrinsic histone acetyltransferase activity. ATP-dependent chromatin-remodeling protein complexes (SWI/SNF/Brm, ISWI, and Mi-2/NuRD) use ATP hydrolysis to make nucleosomal DNA and the histone core accessible to DNA methylation and histone modifications.

3. Epigenetic reprogramming in germ cells

The most differentially methylated regions in imprinted genes of primordial germ cells (PGC) located in the genital ridge become demethylated or "erased" by embryonic day 13 to 14 in both females and males. Prior to this (embryonic days 11.5 or 12.5), PGC are highly methylated and *H19* (a paternally imprinted gene) and *Igf2r* (insulin-like growth factor 2 receptor gene, a regulator of fetal growth and embryonic development) display normal imprinting patterns. Both genes are more methylated in cells with an XY chromosome complement than those with an XX chromosome complement (Durcova-Hills *et al*., 2004). Following demethylation, male PGC in the testicular cords enter mitotic arrest and primary oocytes, surrounded by follicular cells in the fetal ovary, become arrested at the end of meiotic prophase. During spermatogenesis, epigenetic changes of the spermatocyte lineage and the derived postmeiotic haploid spermatids have enabled the use of nuclei of in vitro developed spermatids from spermatocytes precursors to generate normal offspring when injected into mature oocytes (Marh *et al*., 2003).

Genomic imprinting of the sperm and egg genomes is regulated by differential methylation, an activity dependent on DNA methyltransferases. Recent studies of the Dnmt3-Like (*Dnmt3L*) gene have shown that the encoded protein shares homology with Dnmt3a and Dnmt3b in the PHD-zinc-finger domain, but lacks both the highly conserved methyltransferase motifs and enzymatic activity. *Dnmt3L*-deficient females generate mature and functional oocytes, but derived embryos have neural tube and placental abnormalities and are nonviable by mid-gestation. Analysis of DNA methylation patterns of *Dnmt3L*-deficient oocytes shows that genes on different chromosomes (*Igf2r, Mest* (mesoderm-specific transcript) and *Peg3* (paternally expressed gene 3) and several genes in the *Snrpn* (a maternally

imprinted gene) locus) fail to display epigenetic maternalization and the monoallelic expression of all maternally imprinted genes is thought to be lost in the offspring.

The Dnmt3L protein interacts with the Dnmt3 family of DNA methyltransferases and might cooperate with Dnmt3a or Dnmt3b to regulate gamete-specific methylation of imprinted genes in oocytes. In fact, Dnmt3a/Dnmt3b-deficient oocytes also fail to establish epigenetic maternalization. *Dnmt1*-deficient oocytes can establish methylation imprints but cannot maintain imprinting in preimplantation embryos. Therefore, it appears that Dnmt1 is essentially a housekeeping methyltransferase required for maintaining tissue-specific methylation patterns. High levels of the ovarian Dnmt1o accumulate in the oocyte nuclei during the follicular growth phase, when genomic imprinting has been established. Like Dnmt1, Dnmt1o is a housekeeping DNA methyltransferase.

In the male, *Dnmt3L* gene deficiency results in spermatogenesis arrest and sterility due to spermatogonia entering meiosis and being killed by an asynapsis checkpoint just prior to pachytene (Bourc'his and Bestor, 2004). In the female, in contrast, mature and functional oocytes are produced in the *Dnmt3L* deficient mutant. *Dnmt3a* knockout male mice display testes with abnormal meiotic prophase spermatocytes and few mature sperm. In addition to DNA methylation, histone modifications are critical for spermatogenesis. Histone methyltransferase *Suv39h1* and *Suv39h2*-deficient mice are sterile because of meiotic arrest at the pachytene stage of meiotic prophase. These examples emphasize the impact of epigenetic modifications in male and female fertility.

DNA methylation and histone H3-K9 methylation during spermatogenesis correlate with histone deacetylation. Somatic histones are hyperacetylated in spermatogonia and in pre-leptotene spermatocytes but acetylated histones are not detected from leptotene on and in round spermatids. It appears that DNA methylation and histone modifications play a role in modulating meiotic chromosome architecture and in ribosomal and nonribosomal transcription activity. In summary, the timing and extent of remethylation following methylation erasure in PGC is slightly different during oogenesis and spermatogenesis (Figure 1). In the male, remethylation begins in prospermatogonia (gonocytes) by embryonic day 15 to 16 and continues throughout spermatogenesis. Therefore, remethylation takes place before mitotic amplification of the spermatogonial stem cell lineage at the time of puberty. Two representative genes, *H19* and *Mest*, display developmental epigenetic paternalization: both genes are unmethylated in fetal prospermatogonia, *Mest* remains unmethylated throughout spermatogenesis, and *H19* methylation first appears in spermatogonia and is maintained throughout spermatogenesis (Kerjean *et al*., 2000). In the female, remethylation is observed during the growth of oocytes, a prolonged developmental process enabling sequence methylation at different time points. Although germ cell–specific DNA methyltransferases have not been identified, Dnmt3a and Dnmt3b are good candidates (Kaneda *et al*., 2004).

4. Epigenetic reprogramming in preimplantation embryos

After fertilization, the chromatin of the paternal genome undergoes changes consisting in the replacement of protamines by acetylated histones and, from some

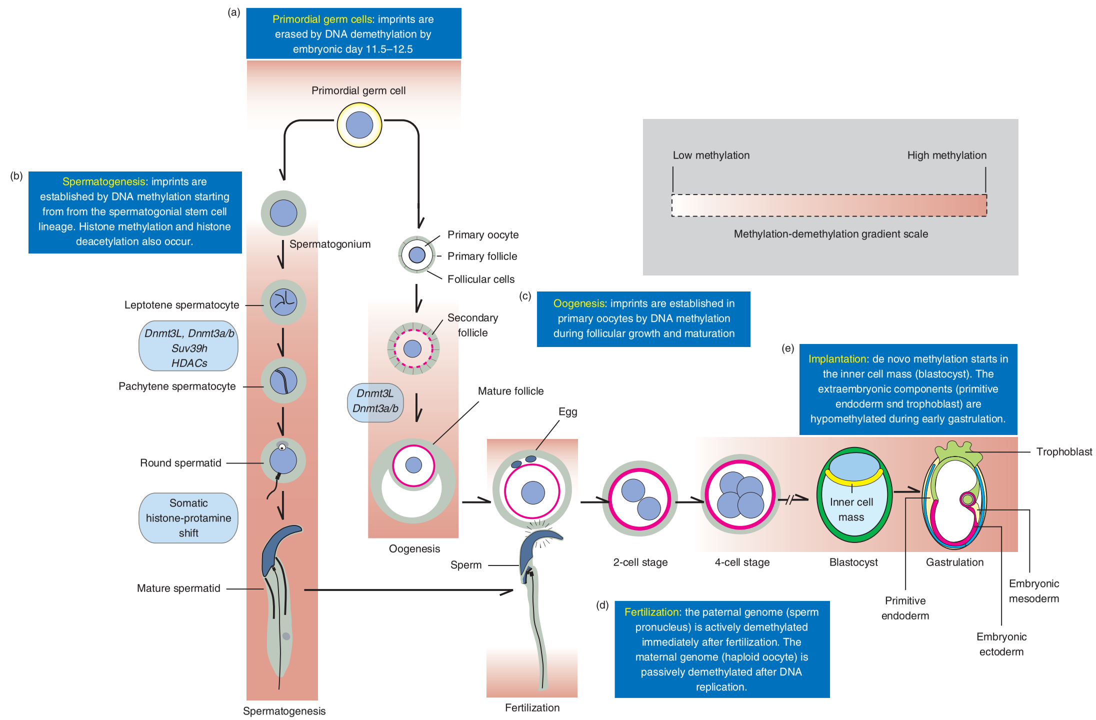

Figure 1 Epigenetic reprogramming during gametogenesis and early embryo implantation (mouse). (a) Demethylation at imprinted loci erase parental imprinting marks in primordial germ cells by embryonic day 11.5–12.5. (b) During spermatogenesis, methyltransferases Dnmt3a and Dnmt3b, in association with Dnmt3L, start to reestablish paternal methylation from spermatogonia on. In addition, histone hypoacetylation-deacetylation – controlled by histone deacetylases (HDACs) – and histone methyltransferases, including Suv39 h, regulate chromatin organization and transcription activities. During spermiogenesis, somatic histones are gradually replaced by transient basic proteins and finally by protamines. Consequently, the nucleosomal beaded chromatin pattern is replaced by smooth chromatin fibers and the genome becomes transcriptionally silent. (c) During oogenesis, maternal-specific genomic imprints are reestablished in the DNA of the oocyte starting during follicular growth and continuing throughout follicle maturation by the de novo activity of methyltransferases Dnmt3a, Dnmt3b, and Dnmt3 L. (d) Immediately after fertilization, the paternal genome (sperm pronucleus) in the zygote is demethylated by an active mechanism. Demethylation of the maternal genome (egg pronucleus) takes place by way of a passive mechanism after DNA replication has occurred. Chromatin decondenses and transcription activities of the zygote, essential for early development, take place. Most of the methylation marks inherited from the male and female gametes are erased by the blastocyst embryonic stage (embryonic day 3.5). (e) During early implantation, the embryonic DNA methylation patterns are established in a lineage-specific manner by de novo methylation starting in the inner cell mass of the blastocyst. DNA methylation levels increase in the primitive ectoderm. The DNA of extraembryonic cells (primitive endoderm and trophoblast) remains hypomethylated. Specific parental imprinted genes protected from demethylation are not indicated for clarity. Diagram not to scale. Data compiled from Reik *et al*. (2001), Kierszenbaum (2002), Lucifero *et al*. (2002), and Li (2002)

evidence, DNA demethylation by an active mechanism that is completed before DNA replication. Some sequences in the paternal chromosomes are protected from demethylation, in particular, the imprinted genes *H19* and *RasGrf1* . The maternal genome is demethylated by a passive mechanism dependent on DNA replication. Dnmt1 is not present in the nucleus and, therefore, passive demethylation occurs. In the eight-cell embryo (mouse), Dnmt1 reappears in the nucleus. At the time of implantation, both the paternal and maternal genomes are remethylated with the participation of Dnmt3a and Dnmt3. Variations in the methylation of imprinted genes in embryonic and extraembryonic cell lineages are characteristic. The postzygotic demethylation and remethylation sequence (mimicking to some extent the reprogramming saga of the germ cell lineage) presumably removes epigenetic modifications acquired during gametogenesis. An important issue is the consequence of using somatic nuclei from adult and embryonic donors during animal cloning. Somatic donor nuclei contain a highly methylated genome, a departure of the precise postzygotic demethylation-remethylation timely sequence. Although somatic nuclei are reprogrammed in clones, the timing and efficiency of demethylation-remethylation of genes critical for cellular differentiation may differ, thus leading to developmental abnormalities and lethality.

Short Specialist Review

Epigenetics and imprint resetting in cloned animals

Sigrid Eckardt, Satoshi Kurosaka and K. John McLaughlin
University of Pennsylvania, Kennett Square, PA, USA

1. Introduction

Since virtually all cells of an individual animal contain the same genetic information, the diversity in differential gene activity required for the development and formation of specialized cells must be ensured by mechanisms that do not involve changes in genomic sequence while efficiently activating or silencing certain genes. These "mitotically and/or meiotically heritable changes in gene function that cannot be explained by changes in DNA sequence" (Russo *et al*., 1996) are referred to as epigenetic, and include the modification of the genome by DNA methylation, the modification of histones, and the adoption of specific chromatin structures (Jaenisch and Bird, 2003; Reik *et al*., 2003). Although epigenetic modifications normally establish a stable cell identity, this cellular memory can be erased or altered. The development of clones from differentiated nuclei establishes that the ooplasm can create a substitute for the zygotic epigenotype from a somatic cell nucleus. Normally, the genome is "reset" during germline development, such that the gametic genomes are prepared to execute a developmental program once the fertilization and remodeling into a zygotic genome has occurred (Renard, 1998).

Germline reprogramming also involves the erasure and establishment of genomic imprints that regulate parent-of-origin-dependent gene expression (Mann, 2001). Apparently, exposure of a somatic nucleus to the ooplasm is sufficient to remodel its epigenetically distinct phenotype to one that is similar enough to that of the zygote, permitting development while bypassing reprogramming events that occur in the germline (Figure 1). Poor development, survival, frequent defects, and gene expression errors prevalent in mammalian clones (Ogura *et al*., 2002; Rideout *et al*., 2001; Wakayama and Yanagimachi, 1999b; Wells, 2003), and possibly the diminishing efficiency when cloning from clones for multiple generations (Wakayama *et al*., 2000), suggest that epigenetic reprogramming of somatic cell nuclei in clones is usually flawed or incomplete.

2. Genomic imprinting

The failure of clones, and the abnormalities observed in those that develop, are presumably due to incomplete reprogramming that affects gene expression. Clones

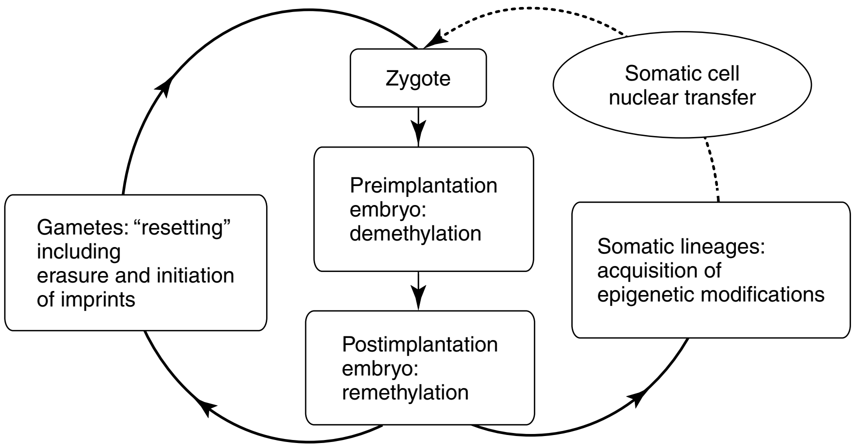

Figure 1 Somatic cell nuclear transfer bypasses germline reprogramming

exhibit gene expression abnormalities at several developmental stages (Daniels *et al*., 2000; Daniels *et al*., 2001; Humpherys *et al*., 2002; Inoue *et al*., 2002; Wrenzycki *et al*., 2001) including essential embryonic genes (Boiani *et al*., 2002; Bortvin *et al*., 2003). Genes subject to parental allele-specific imprinting have been considered key to the problems in clone development, as loss of the parental-specific imprint would require the germline passage to be reestablished (Jaenisch, 1997). Allelic expression of imprinted genes is regulated by parental-specific imprinting marks that are set in the germline, some of which involve differential methylation of regulatory regions. Dysregulation of imprinted genes has severe consequences on development, apparent in the early death of uniparental embryos (Barton *et al*., 1984; Mann and Lovell-Badge, 1984; McGrath and Solter, 1984; Surani *et al*., 1984), the abnormalities observed in those with uniparental duplications of chromosomal regions (Cattanach, 1986) and targeted disruption of imprinted gene expression (DeChiara *et al*., 1990; Eggenschwiler *et al*., 1997; Lau *et al*., 1994; Leighton *et al*., 1995). Abnormalities associated with disruption in the expression of imprinted genes regulating fetal growth, including insulin-like growth factor 2 (Igf2) and Igf2 receptor (Li *et al*., 1998; Reik and Maher, 1997), are similar to some of the most common phenotypes of clones: respiratory failure (Hill *et al*., 1999; Ogura *et al*., 2002; Wells, 2003), fetal overgrowth (Young *et al*., 1998), increased birth weight (Eggan *et al*., 2001), and placental hypertrophy (Hill *et al*., 2000; Humpherys *et al*., 2001; Ono *et al*., 2001; Tanaka *et al*., 2001; Wakayama and Yanagimachi, 1999a; Wakayama and Yanagimachi, 2001). Several imprinted genes are indeed expressed at abnormal levels in clones both at fetal or perinatal stages, but particularly so in the placentae (Humpherys *et al*., 2002; Inoue *et al*., 2002). The imprinted genes commonly implicated in the dysregulation of fetal growth, Igf2, Igf2r, and H19, are, however, expressed at normal levels and presumably not implicated (Humpherys *et al*., 2002; Inoue *et al*., 2002; Wells, 2003). Additionally, the abnormal expression levels observed in several imprinted genes analyzed were not associated with an imbalance in the allele specificity (Humpherys *et al*., 2002; Inoue *et al*., 2002). Therefore, the aberrant expression of imprinted genes seems to

be stochastic with no apparent correlation to phenotypes, at least in those clones that develop to midgestation or later. As this proportion of clones represents a minority of those generated, it does not preclude that dysregulation of imprinted genes contributes to the death of the large high proportion of clones that occurs early in gestation.

Analysis of clones at early developmental stages, such as the blastocyst, allows a more representative analysis of epigenetic and gene expression changes in the majority of clones, presumably indicative of reprogramming. In the mouse, most clones at the blastocyst stage retain or emulate the allele specificity of expression of imprinted genes with monoallelic expression patterns in both somatic cells and the early embryo, such as H19, Meg3, or Snrpn (Mann *et al*., 2003). This may reflect either continuation or a correct reestablishment of the allele-specific imprint. However, the differential methylation patterns of control regions involved in the regulation of allelic expression appear not to be established correctly for H19 and Snrpn. This may not influence preimplantation stage expression but could predict the loss of allele-specific expression in postimplanation development. For two autosomal imprinted genes that differ in expression between preimplantation stage and the soma, Ascl2 and Igfr2, being expressed biallelically in the early embryo but monoallelically in somatic cells, expression patterns are random with both mono- and biallelic expression patterns in clone mouse blastocysts. This suggests that reprogramming required for regulation of allele-specific expression often fails after somatic cell nuclear transfer. The proportion of clones at the blastocyst stage with correct reprogramming/expression of autosomal imprinted genes is very low (4%; Mann *et al*., 2003). Methylation and expression of imprinted genes are, however, altered in embryos due to culture in vitro and possibly have long-term effects on development (Doherty *et al*., 2000; Khosla *et al*., 2001; Young *et al*., 2001). Clones require considerable periods of in vitro culture, and are apparently not an exception to this phenomenon (Mann *et al*., 2003).

3. X inactivation

In contrast to autosomal imprinted genes, faithful recapitulation from mono- to biallelic activity has been observed in mouse clones with respect to X inactivation. The inactive X from a female somatic donor nucleus becomes activated in clones during preimplantation stages, followed by random X inactivation in the epiblast (Eggan *et al*., 2000). Since nonrandom inactivation is observed in the trophectoderm lineage of midgestation clones, with preferential inactivation of the previously inactive X chromosome of the somatic donor nucleus, it appears that an X chromosome silenced randomly in the epiblast carries an imprinting mark that is functionally equivalent to that of the paternal X chromosome of the zygotic genome. Placental tissue of perinatal bovine clones exhibited preferential inactivation of one X chromosome in viable clones, contrasting with biallelic activity in clones that died at birth, suggesting a similar recognition process in bovine clones but also a possible correlation of biased X inactivation in extraembryonic tissues with viability (Xue *et al*., 2002). However, as cloning of mammals from female versus male somatic

cells is similar in efficiency, X inactivation is apparently not a limiting factor in clone development (Heyman *et al*., 2002; Kato *et al*., 2000).

4. Global methylation changes in clones

The developmental stages subsequent to the stage at which nuclear transfer is performed, normally include a sequence of major changes in the methylation status of the zygotic genome. In murine and bovine embryos, the paternal genome appears to be rapidly demethylated within hours of fertilization ("active" demethylation), while demethylation of the maternal genome occurs in a replication-dependent manner during cleavage stages ("passive" demethylation) (Dean *et al*., 2001; Mayer *et al*., 2000; Oswald *et al*., 2000; Rougier *et al*., 1998). Global de novo methylation of the hypomethylated embryonic genome occurs at late preimplantation stages and after implantation. The recapitulation of stage-specific methylation patterns in somatic cell clones of several species is inconsistent, which can be interpreted as errors in reprogramming. Analysis of global methylation of genomic repetitive elements in the early cleavage (Bourc'his *et al*., 2001), morula (Dean *et al*., 2001), and blastocyst (Kang *et al*., 2001) stage, bovine clones revealed abnormally high levels of methylation, similar to those of the somatic donor nuclei. While observations differ in respect to conservation (Dean *et al*., 2001) or absence (Bourc'his *et al*., 2001) of an initial wave of active demethylation, there is a consensus that passive demethylation during early cleavage stages is lacking (Kang *et al*., 2001). Faithful recapitulation of preimplantation-stage-specific methylation changes occurred on one single-copy sequence analyzed (Kang *et al*., 2003) but not on satellite sequences (Bourc'his *et al*., 2001; Kang *et al*., 2001; Kang *et al*., 2002). These contrasts in methylation for different sequences have been ascribed to the structural differences between permanent (satellite sequences) and facultative (unique sequences) heterochromatin (Kang *et al*., 2003). Interpretation of methylation status changes at the early developmental stages cannot predict developmental outcomes, however, the widespread dysregulation of global methylation, particularly in the trophectoderm of bovine clone blastocysts (Kang *et al*., 2002), is consistent with the overall and, in particular, the placental gene expression abnormalities in clones at later developmental stages. Some variation from the normal state of DNA methylation is compatible with postnatal development (Humpherys *et al*., 2001; Ohgane *et al*., 2001). However, major level differences in global methylation coincide with loss of viability, as evident from null mutants for DNA methyltransferase in the mouse (Jaenisch and Bird, 2003) and the observation of genome-wide hypomethylation in the majority of aborted bovine clone fetuses at late gestational stages (Cezar *et al*., 2003).

5. Conclusions

The abnormal or failing development of mammalian somatic cell clones presumably reflects inappropriate gene expression, precipitated by failure to put in place the necessary epigenetic information. It should also be considered that the cloning

efficiency using donor nuclei from less-differentiated cells such as embryonic blastomeres and cells is low, and possibly limited by factors other than reprogramming of gene expression (Cheong *et al*., 1993; Eggan *et al*., 2001; Otaegui *et al*., 1994; Prather *et al*., 1987; Rideout *et al*., 2000; Tsunoda and Kato, 1997; Willadsen, 1986).

Reprogramming of the somatic cell nucleus is typically imperfect, evident at both the level of expression and in the epigenetic modifications of imprinted genes but is possibly due to the retention of characteristics of the somatic cell, at the exclusion of, or conflicting with normal developmental epigenetics. Additional evidence for the maintenance of the epigenome of the donor nucleus stems from studies indicating retention of somatic cell–like metabolism (Chung *et al*., 2002) and gene expression (Gao *et al*., 2003). As the abnormal phenotypes observed in clones coincide with abnormal gene expression but do not necessarily correlate with imprinted gene expression, reprogramming errors are apparently genome-wide (Humpherys *et al*., 2002). This is consistent with the finding that many genes are downregulated in clones. The threshold at which these differences prevent development are unknown, and gene expression and methylation variation in viable clones at term exemplifies that development is somewhat tolerant to variation in epigenetics. To assess the quality of reprogramming, it will be essential to define those epigenetic criteria that not only need to be reset after nuclear transfer but also correlate with viability.

Short Specialist Review

Imprinted QTL in farm animals: a fortuity or a common phenomenon?

Martien A. M. Groenen
Wageningen University, Wageningen, The Netherlands

The analysis of complex multifactorial traits has always been at the forefront in livestock species. Contrary to human and mouse, monogenic traits and disorders are generally easily recognized and removed by culling potential carrier animals. Initially, breeders applied these aspects in the algorithms and programs used to calculate breeding values for these animals, but with the development of detailed linkage maps and high-throughput genotyping systems in the last two decades, it formed the basis for the localization of many loci underlying such complex traits (for a recent overview of identified QTL in pigs and chicken, see **http://www.animalgenome.org/QTLdb/** and **http://acedb.asg.wur.nl/**). Because these traits are quantitative in nature and are being influenced by a large number of genes as well as by environmental factors, they are referred to as quantitative trait loci or QTL. The initial algorithms used to analyze the data from a genome-wide scan, were restricted in considering only Mendelian inheritance and generally a single QTL per individual chromosome. More recently, several groups have started to extend these programs to include epistatic and epigenetic effects as well (Carlborg and Andersson, 2002; Carlborg *et al*., 2003; Knott *et al*., 1998; Jeon *et al*., 1999; Nezer *et al*., 1999; de Koning *et al*., 2000). Population structure and the outbred nature of most livestock breeds make them particularly well suited to address these genetic effects, something that is generally not possible in crosses between inbred laboratory rats and mice.

Although the potential implications of genetic imprinting with regard to quantitative traits in farm animals had already been described by de Vries *et al*. (1994), the interest for epigenetic effects in livestock species was particularly triggered by the identification of the callipyge locus in sheep. The callipyge locus was observed to be segregating in his herd by a sheep breeder in Oklahoma in 1983. The mutation results in an exceptional muscularity, and a subsequent genetic analysis revealed an exceptional behavior of this locus. Although the segregation of the callipyge phenotype clearly indicated an underlying mechanism of imprinting, the fact that homozygous carriers of the callipyge mutation did not express the callipyge phenotype was an intriguing observation and the effect was referred to by the authors as polar overdominance (Cockett *et al*., 1996). In subsequent studies, it was shown

that the callipyge mutation is located in a potential longe-range control element (LRCE) located between a group of paternally expressed (*DLK1* and *PEG11*) and maternally expressed (*GTL2* and *MEG8*) genes (Freking *et al*., 2002). The current working hypothesis for the observed polar overdominance at the callipyge locus is that (one of) the paternally expressed genes has a strong positive effect on muscle development and that (one of) the maternally expressed genes is a negative regulator of the paternally expressed gene(s). In this model, the LRCE is a gain-of-function mutation that results in an increase of both the maternally and paternally expressed genes (Georges *et al*., 2003). Although the callipyge mutation clearly affects a quantitative trait, its large effect on the phenotype enabled the analysis of the locus as a monogenic trait rather than a QTL.

The interest with regard to imprinting in relation to QTL was further boosted by the simultaneous independent findings of two research groups that a QTL on the tip of the p-arm of pig chromosome 2 (SSC2), affecting muscle mass and fat deposition, showed clear evidence of being maternally imprinted (Nezer *et al*., 1999; Jeon *et al*., 1999). Subsequent research recently led to the identification of a mutation in a regulatory site of the maternally imprinted gene *IGF2* as being the causative mutation underlying the imprinted QTL (Van Laere *et al*., 2003). The mutation is located in a CpG island located within intron 3 of the *IGF2* gene, which results in the abrogation of the binding of a repressor, resulting in an increased expression of the *IGF2* gene in pig muscle.

Triggered by the findings of the callipyge and *IGF2* gene, de Koning *et al*. (2000) decided to include a parent-of-origin effect in their statistical model for the genome-wide identification of QTL in a divergent cross between Chinese Meishan with European white pigs. Their results indicated a surprisingly large number of QTL that seemed to be affected by either maternal or paternal imprinting. The paternally expressed QTL on SSC2 in that study was recently (Jungerius *et al*., 2004) shown to be caused by the same mutation in *IGF2* that was identified by Van Laere *et al*. (2003). This mutation, however, was not responsible for the imprinted QTL on SSC2 affecting teat number (Hirooka *et al*., 2001; Jungerius *et al*., 2004). Additional analysis by these researchers and by others using another similar cross resulted in the further identification of several QTL for different growth-related traits on a number of different chromosomes (Rattink *et al*., 2000; De Koning *et al*., 2001; Milan *et al*., 2002; Desautes *et al*., 2002; Quintanilla *et al*., 2002).

Why do so many QTL seem to be affected by imprinting? There are several aspects to consider in dealing with this question (*see* Article 37, **Evolution of genomic imprinting in mammals**, Volume 1). One of the reasons that might cause the unexpectedly large number of imprinted QTLs is due to the nature of the traits being studied in these studies, which mainly were related to body composition and growth. The parental conflict hypotheses for imprinting (Sleutels and Barlow, 2002) suggests that there is a battle between male and female based on a trade-off for the survival of offspring versus that of the survival and fecundity of the mother. Consequently, genes affecting growth might be expected to be affected by imprinting at a higher frequency then the average gene. The fact that the paternally expressed genes identified for callipyge and on SSC2 have a strong positive effect on growth would support this hypothesis. However, this is not the case for all the

observed QTL effects. Furthermore, an imprinted QTL controlling susceptibility to trypanosomiasis with no clear relevance to growth was recently identified in mice (Clapcott *et al*., 2000). The experimental design of the QTL study and, in particular, the family structure of the population being studied has been shown to strongly affect the chance of identifying spurious imprinted QTL (De Koning *et al*., 2002). In particular, when the number of F1 animals is small or for smaller QTL effects when the founder lines are not fixed for different QTL alleles, spurious detection of imprinted QTL is a serious problem. A skewed distribution of uninformative markers between the male and female parents potentially could also result in the spurious identification of imprinted QTL in these crosses, although this pitfall could be excluded in the pig studies described above. Finally, other phenomena such as epistatic interactions between different genes might further complicate the correct identification of imprinting effects. Recently, Carlborg *et al*. (2003) have shown that epistatic effects also seem to play a major role in QTL identified for a large number of growth related traits.

Although several of the identified imprinted QTL effects are likely to be spurious effects, the studies described above provide accumulating evidence that imprinting plays a more important role in multifactorial traits than previously anticipated. Furthermore, the identification of the callipyge and *IGF2* mutations provide further insight into the importance of genetic variation within regulatory regions on quantitative traits. For animal breeding practice, the identification of major imprinted loci affecting body composition has several implications. It calls for a revision of the breeding value evaluation methods and breeding strategies that are currently solely based on the assumption of a large number of genes showing Mendelian expression. Detecting the QTL and confirming the mode of inheritance in commercial populations would open important new opportunities for pig-breeding companies. Imprinted QTL for fatness, for example, offers the opportunity to produce crossbred sows that have higher levels of fat reserves (beneficial for their health and reproduction), while their offspring have lower amounts of fat (requested by the consumer).

The results from the QTL studies in farm animals clearly have emphasized the importance of the inclusion of statistical testing for imprinting in the analysis of complex traits not only in animal genetics but in human medical genetics as well. Subsequent detailed molecular analysis and definite proof of the imprinting effects have to await the identification of the underlying genes responsible for the observed QTL effects.

Short Specialist Review

Variable expressivity and epigenetics

Marnie E. Blewitt and Emma Whitelaw

University of Sydney, Sydney, Australia

1. Introduction

It is clear that the phenotype of an organism cannot be completely described by its genotype alone. The phenotypic differences between humans, or between individuals of other species, appear to be greater than can be explained by the frequency of single nucleotide polymorphisms (SNPs) even when the environment is "controlled". In some cases, we know that the variation in phenotype can be ascribed to epigenetic rather than genetic differences. Epigenetic changes involve modifications to the DNA, such as methylation of cytosine residues, and modifications to the chromatin, such as acetylation and methylation of histone proteins. One of the underlying aspects of epigenetic control of gene expression is that it is stochastic, that is, there is a certain probability of a particular epigenetic state being established at a particular locus, but this is not necessarily 100%, and has profound implications on phenotype.

2. Variegation

For centuries, variegated appearances have been observed in plants and mammals. Variegated leaves and brindle coat colors in dogs are good examples. In humans, the iris often has a flecked appearance. Variegation can be defined as the differential expression of a particular gene among cells of the same cell type. The more recent finding of variegation in the expression of transgenes has provided a tractable experimental system for studying the molecular basis of this phenomenon in mammals (Mintz and Bradl, 1991; for review, Martin and Whitelaw, 1996). For reasons that remain unclear, transgenes appear to be particularly sensitive to variegation, and, at least in these cases, differential expression of the foreign DNA element is the result of differential transcriptional activity. The differential transcriptional activity correlates with epigenetic modifications at the transgene locus. In general, expressing cells are found to display hypomethylation of cytosine residues and an open chromatin state at the transgene promoter, while nonexpressing or silent cells are found to be hypermethylated at CpG dinucleotides, with a closed chromatin state (Allen *et al*., 1990; Festenstein *et al*., 1996; Garrick *et al*., 1996; Weichman

and Chaillet, 1997; Sutherland *et al*., 2000; Kearns *et al*., 2000). This chromatin compaction is reminiscent of what had already been reported as the molecular basis of a phenomenon called position effect variegation (PEV) in *Drosophila* (Henikoff, 1990), although *Drosophila* lacks CpG methylation.

3. Variable expressivity

Variable expressivity, where a range of expression states is observed among littermates, is another interesting feature of some transgenes. Variable expressivity, also called incomplete penetrance, is a term frequently used by clinicians to describe the feature of diseases where despite several family members being carriers of the disease, only some actually go on to present with symptoms. In these cases, the variable expressivity of the disease is rationalized by differences in quantitative trait loci (QTLs) between family members. However, variable expressivity at transgenes made in genetically identical, inbred strains of mice cannot be so simply explained. Originally, this was reported for transgenes made in mixed genetic backgrounds (Allen *et al*., 1990; Dobie *et al*., 1996), or closed colonies (Sutherland *et al*., 2000; Kearns *et al*., 2000), but these results have also been confirmed in inbred strains, where the individuals are genetically identical (Weichman and Chaillet, 1997). In these cases, transgene expression can range from very high, to variegated, to completely silenced, an unexpected event in isogenic individuals.

4. Subtle parent-of-origin effects

Furthermore, the extent to which a transgene is expressed can be dependent on the parent-of-origin of the transgene. This is often a subtle parent-of-origin effect, which differs from classic parental imprinting (Maggert and Golic, 2002; Preis *et al*., 2003). Classic parental imprinting refers to a situation in which an allele is active when inherited from one parent and inactive when inherited from the other. Subtle parent-of-origin effects refer to situations in which the probability of expression shifts depending on whether the allele has been inherited from the mother or the father. For example, the amount of variegation at the transgene may vary by approximately 20%, depending on parental origin (Preis *et al*., 2003). If the transgene displays variable expressivity, that is, a range of expression states between individuals, then the parental origin can shift the proportion of individuals in each class (Allen *et al*., 1990; Kearns *et al*., 2000). This shift is a probabilistic event, rather than a complete switch in expression, as seen in parentally imprinted alleles.

Recent work on *Drosophila* P transposon insertions has shown that 22 of 23 insertions into the *Drosophila* Y chromosome display subtle parent-of-origin effects (Maggert and Golic, 2002). In this case, the phenotypic assay is eye color, where the amount of variegation between the red and white pigment varies according to the parental origin of the Y chromosome. For some insertion sites, the transgene is expressed more following maternal transmission, and at other sites the reverse is observed. This result implies that large regions of the Y chromosome in *Drosophila* are subject to parent-of-origin effects (Maggert and Golic, 2002). In mammals, it

is also possible that large portions of the genome are subtly imprinted since small effects could easily have been overlooked.

It is now clear that variegation, variable expressivity, and subtle parent-of-origin effects are not peculiar to transgenes but are seen in endogenous alleles in mice, plants, and *Drosophila*. To date, the reported alleles that display these effects produce visual phenotypes. It is still unclear how common such alleles are, and whether they exist in humans. In plants and mammals, these alleles are now termed metastable epialleles (Brink, 1960; Matzke *et al*., 1994; Hollick *et al*., 1995 and Rakyan *et al*., 2002).

Examples of murine metastable epialleles include *agouti viable yellow* (A^{vy}) (Perry *et al*., 1994), *agouti intracisternal A particle yellow* (A^{iapy}) (Michaud *et al*., 1994), and *agouti hypervariable yellow* (A^{hvy}) (Argeson, 1996), also *axin fused* ($axin^{Fu}$) (Reed, 1937; Ruvinsky and Agulnik, 1990; Zeng *et al*., 1997), *axial defects* (Essien *et al*., 1990), *disorganization* (Hummel, 1959), and *murine CDK5 activator binding protein IAP* ($mCABP^{IAP}$) (Druker, *et al*., 2004). It is interesting to note that A^{vy}, A^{iapy}, A^{hvy}, $axin^{Fu}$, and $mCABP^{IAP}$ all arose as a result of the stable integration of a retrotransposon. In the case of the *agouti* alleles and $axin^{Fu}$, the variable expressivity arises as a direct result of variable activity at a cryptic promoter in the retrotransposon long terminal repeat (LTR), which reads out into the adjacent DNA (Michaud *et al*., 1994; Perry *et al*., 1994 and Argeson, 1996). It is possible that all endogenous metastable epialleles will turn out to be under the control of nearby retrotransposons. Given that over 9% of the human genome has been classified as retrotransposon-like (International Human Genome Sequencing Consortium, 2001), metastable epialleles may also be present in reasonable numbers in humans.

The A^{vy} allele is perhaps the best-characterized metastable epiallele. In this case, the allele results from an intracisternal A particle (IAP) insertion, upstream of the *agouti* gene (Duhl *et al*., 1994). When the cryptic promoter in the IAP LTR is active, it causes constitutive expression of the *agouti* gene (Duhl *et al*., 1994). Agouti is a signaling molecule that causes a shift in pigment production from black to yellow. Normally, the *agouti* gene is under the control of hair-cycle-specific promoters, and is produced for only a short period in the hair growth cycle, to produce a subapical yellow band on an otherwise black hair. The resultant mouse appears brown (an agouti coat). However, when the *agouti* gene is constitutively expressed, a completely yellow coat results, along with other pleiotropic effects including obesity and diabetes. Sometimes, a genetically identical mouse will have an agouti-colored coat (termed pseudoagouti). In this case, the cryptic promoter is silent, and CpG-methylated, and the *agouti* gene undergoes normal spatiotemporal expression (Morgan *et al*., 1999). A spectrum of intermediate mottled phenotypes, where there is variegated A^{vy} allele expression, is also observed (see Figure 1).

The A^{vy} allele displays a subtle parent-of-origin effect (Morgan *et al*., 1999), as do many other endogenous murine metastable epialleles (Reed, 1937; Belyaev *et al*., 1981; Essien *et al*., 1990; Duhl *et al*., 1994; Argeson, 1996; Rakyan *et al*., 2003). In this case, a yellow female produces a greater proportion of yellow offspring than a yellow male. There is a 15% difference in the proportion of pseudoagouti mice produced from these reciprocal crosses (Morgan *et al*., 1999).

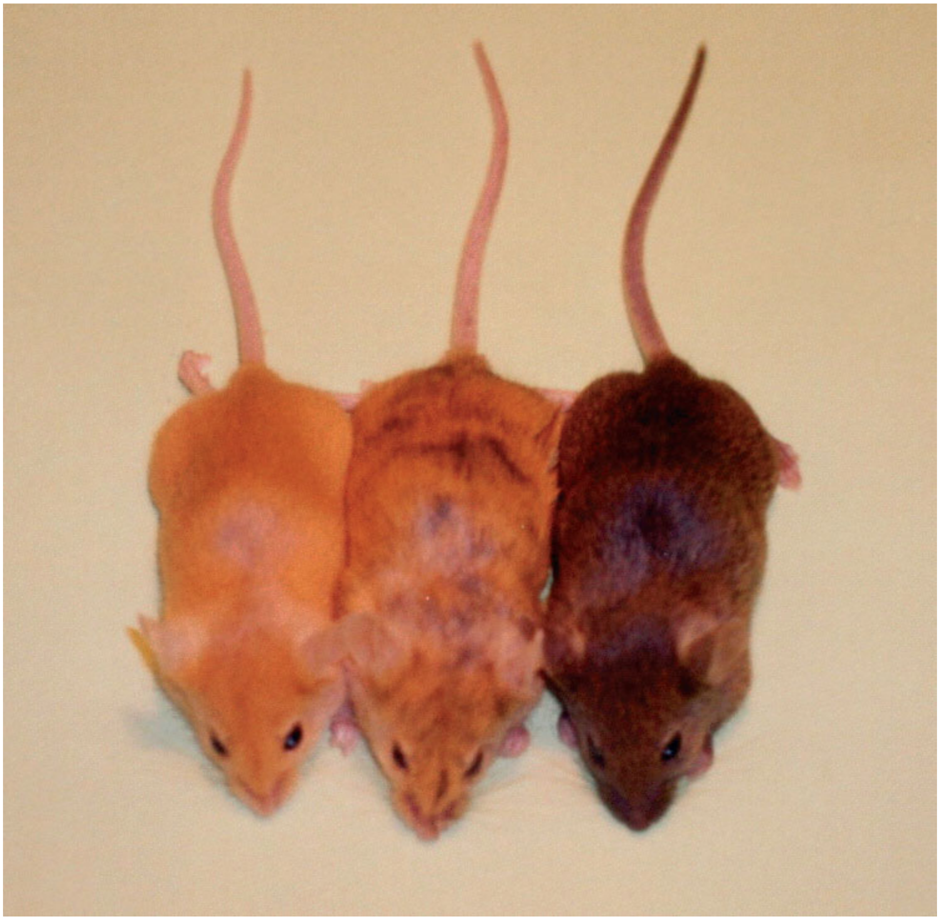

Figure 1 Genetically identical mice carrying the A^{vy} allele display variegation and variable expressivity. The mouse on the left is termed yellow, the middle mouse is termed mottled, and the mouse to the right is termed pseudoagouti

Again, this is a small, but significant shift in the spectrum of coat color phenotypes seen at the A^{vy} allele, which is dependent on parental origin (see Figure 2).

5. Transgenerational epigenetic inheritance

An additional effect seen at some murine transgenes (Hadchouel *et al*., 1987; Allen *et al*., 1990; Kearns *et al*., 2000; Sutherland *et al*., 2000) and some metastable epialleles, including the A^{vy} allele, is transgenerational epigenetic inheritance (Belyaev *et al*., 1981; Wolff, 1978; Morgan *et al*., 1999; Rakyan *et al*., 2003). A yellow-coated A^{vy} female produces more yellow offspring than a pseudoagouti female, despite being genetically identical (Morgan *et al*., 1999; see Figure 2). That is, there is some memory of the phenotype, and, therefore, the epigenotype of the mother. The mechanism of epigenetic inheritance is not known, but it seems likely

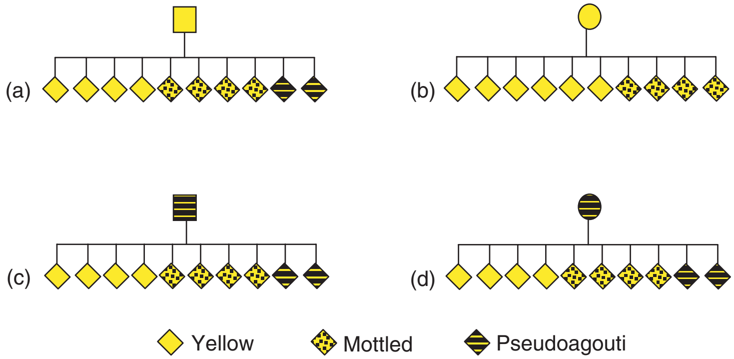

Figure 2 Schematic pedigrees of coat color inheritance at the A^{vy} allele. Mice heterozygous for the A^{vy} allele mated with congenic animals, carrying a null *agouti* allele. Only offspring carrying the allele are displayed. Comparing (a) and (b), there are more yellow mice observed following female transmission of the allele from a yellow parent. This is a subtle parent-of-origin effect, which shifts the proportion of each phenotype of offspring. Comparing (b) and (d), the yellow female produces more yellow offspring than the pseudoagouti female, so the range of phenotypes of the offspring is influenced by the phenotype of the dam. This is transgenerational epigenetic inheritance

that there is incomplete clearing of the epigenetic marks between generations. Again, it is unclear how often epigenetic inheritance may be occurring, but it certainly has profound implications on the inheritance of phenotype in general. Interestingly, although epigenetic inheritance can occur through the male germline (Rakyan *et al*., 2003), it is more common following female transmission. It is interesting to consider whether this mode of inheritance has some adaptive value. In higher organisms, the mother will often stay with the young after birth. It may be advantageous for the phenotype of the offspring to be more closely related to that of the mother, who is presumably well adapted to the surrounding physical environment.

A recent finding in *Drosophila* suggests that epigenetic inheritance of chromatin state could provide a mechanism for rapid evolution of morphological traits (Sollars *et al*., 2003). Sollars and coworkers found that epigenetic variants produced de novo, can cause phenotypic variations. The variants were produced by genetically altering levels of chromatin proteins. Unexpectedly, the phenotypic variation could be inherited through the female germline for successive generations, in the absence of the original genetic mutation. The inheritance resulted after only one meiotic generation, several generations faster than is required for genetic variation to drive to fixation (Rutherford and Henikoff, 2003).

The existence of variable expressivity and epigenetic inheritance, raises the possibility that phenotypic variation in humans may not be all QTL-based. Moreover, some of the evolution of quantitative traits may have been due to epigenetic, rather than genetic changes. Consider a situation in which an allele displays variable expressivity, due to differences in epigenetic state of the allele. One of the phenotypes may be selected owing to environmental change, and inherited through the

germline owing to transgenerational epigenetic inheritance. However, since epigenetic inheritance is never complete, variation is not lost, which may allow for a more plastic adaptation than the selection of genetic variation affords.

Short Specialist Review

Evolution of genomic imprinting in mammals

Hamish G. Spencer
University of Otago, Dunedin, New Zealand

1. Introduction

Genomic imprinting is the name of the form of non-Mendelian gene expression in which the two copies of a gene at a locus have different levels of expression. The archetypal case is that of insulin-like growth factor 2 (IGF-2) in which the maternal copy is silent in most fetal tissues, with only the paternally inherited copy being transcribed. Some 60 or so mammalian loci are currently known to be imprinted (Morison *et al*., 2001), but there is little consensus about the proportion of the genome subject to imprinting. By silencing (or at least downregulating) one copy of a gene, imprinting negates (or reduces) what is considered to be the major advantage of diploidy in mammals, namely, the ability to mask recessive deleterious mutations. Thus, the evolution of imprinting from an ancestral state of standard Mendelian (i.e., biallelic) expression appears paradoxical, apparently reducing an individual's fitness. Several hypotheses seeking to resolve this paradox have been proposed by a number of authors. Here we examine a number of the more plausible ideas, highlighting their various strengths and weaknesses. In brief, however, no single hypothesis appears able to explain all the observations.

2. Prevention of parthenogenesis and the ovarian time-bomb hypothesis

The oldest ideas note that if different loci are oppositely inactivated (i.e., the maternal copy is transcribed at one locus and the paternal copy at another), imprinting at essential loci would require both paternal and maternal contributions to the developing zygote, thereby preventing parthenogenesis. Indeed, recent experiments with mice show that if appropriate expression at the normally imprinted H19 and Igf2 loci occurs, at least some parthenogenetic embryos can survive to adulthood and reproduce (Kono *et al*., 2004). The observed absence of any parthenogenetic mammalian species consequently led some authors to argue that imprinting may have evolved for this purpose. Parthenogenesis is considered to be disadvantageous because it stops the genetic recombination that occurs as a

consequence of sexual reproduction. Parthenogenetic lineages are inclined to be evolutionary dead ends, lacking the ability to respond to novel selection pressures.

The main problem with this argument, however, is that it is "group-selectionist": the purported advantage of avoiding parthenogenesis accrues to the species, not to an individual. Indeed, an individual with parthenogenetic abilities might have a selective advantage, able to reproduce even in the absence of suitable mates. This selection for parthenogenesis at the level of the individual would subvert selection against it at the level of the species. In most cases of conflict between selection pressures in opposite directions at different levels, selection at the lower level – for instance, individuals rather than species – prevails. Thus, prevention of parthenogenesis for the good of the species is not considered a likely cause of the evolution of imprinting in mammals.

Nevertheless, an individual-level advantage for avoiding parthenogenesis has been suggested by Varmuza and Mann (1994). They argued that a haploid egg spontaneously developing in an ovary would amount to ovarian cancer, and imprinting may have evolved to prevent such a scenario. Inactivating the maternal copy of a growth-enhancing gene would defuse this "ovarian time bomb". Iwasa (1998) pointed out that the same protection is afforded by upregulating the maternal copy of a growth-inhibiting gene. Moreover, the level of expression in the diploid developing zygote can be maintained by concomitantly downregulating the paternal copy of this same gene, possibly to the point of silencing it. Thus, the ovarian time-bomb hypothesis predicts that growth-affecting genes active in the early stages of embryogenesis are likely candidates for imprinting and that growth enhancers should be maternally inactivated, whereas growth inhibitors should be paternally silenced. And indeed, this prediction is often met: the growth-enhancing Igf2 is maternally inactivated in fetal tissues in all mammalian species examined so far, and the growth-inhibiting Igf2r is paternally inactivated in mice and rats (but not in humans).

Mathematical modeling of the ovarian time-bomb hypothesis (Weisstein *et al*., 2002) implies that the verbal hypothesis is plausible: the selection pressures envisaged could lead to the evolution of imprinting. The modeling shows also that the selection pressure required to lead to the evolution of imprinting need not be very strong, contradicting the objection that ovarian cancer was too rare to be worth the cost of the loss of functional diploidy. Nevertheless, it is less clear why so many loci should be imprinted: surely, the imprinting of one or two critical loci would provide sufficient protection. The flip side of this problem is that the hypothesis at least offers a weak explanation for why not all growth-affecting genes important in early development (e.g., IGF1) are not imprinted. Finally, the hypothesis offers no explanation for genes that are not involved in early development.

3. The genetic-conflict hypothesis

Perhaps the best-known explanation for the evolution of imprinting is that invoking the different, conflicting genetic interests of mothers, fathers, and their offspring (Haig and Graham, 1991; Haig, 1992). A mammalian mother is equally related to all the offspring in a single (and subsequent) pregnancies, so her genetic contribution to the next generation is maximized by ensuring the survival of as many of these

offspring as possible. To at least the first level of approximation, these genetic interests are best served by equally dividing the nutrients and care she provides among these offspring. One way to accomplish this goal would be to turn off any growth-enhancing genes in her offspring, so she can control the transfer of her various resources. A father's genetic perspective is quite different, however, because most mammals have some degree of multiple paternity. A mammalian father has no assurance that all the offspring born to a female with which he has mated will be his. Consequently, his genetic success is greater if somehow his offspring obtain more maternal resources, maybe at the expense of any half-sibs or even the mother herself. Inactivating the paternal copy of a growth-inhibiting gene would achieve that end.

Thus, the genetic-conflict hypothesis makes the same predictions as the ovarian time-bomb hypothesis about the sorts of loci likely to be imprinted (i.e., growth-affecting genes important in fetal development) and the direction of imprinting (i.e., maternal inactivation of growth enhancers and paternal silencing of growth inhibitors). Mathematical modeling by various groups confirms the basic plausibility of the hypothesis (Spencer *et al*., 1999). Some modeling (Spencer *et al*., 1998) predicts that under certain circumstances, a locus can be polymorphic in imprinting status, with some individuals having two active copies of the genes and others just one. Indeed, two loci, the Wilm's tumor suppressor, WT1 (Jinno *et al*., 1994), and the serotonin-2A (5-HT_{2A}) receptor, HTR2A (Bunzel *et al*., 1998), appear to fulfill this prediction. Importantly, this prediction differs from that derived from modeling of the ovarian time-bomb hypothesis, so these observations lend important support to genetic conflict over the ovarian time bomb. The genetic-conflict hypothesis can also apply in arenas other than fetal development, for example in postnatal care, and so the range of loci likely to be imprinted by this mechanism is greater than under the ovarian time bomb. This prediction appears largely, but not completely, fulfilled (Tycko and Morison, 2002). Nevertheless, the genetic-conflict hypothesis is less able to explain why other growth-affecting genes such as Igf1 are not imprinted.

4. Differential selection on males and females

We have only a limited number of observations on imprinting at sex-linked loci. Indeed, the best known simply infer the presence of imprinting from observations of chromosomal abnormalities, especially X-chromosome monosomy in mice (*see* Article 46, **UPD in human and mouse and role in identification of imprinted loci**, Volume 1). The parental origin of the single X in these XO mice has significant growth effects: if it is paternally derived, the mice are developmentally retarded (Jamieson *et al*., 1998), implying the presence of a paternally inactivated growth enhancer. Thus, the direction of imprinting at X-linked loci appears to be opposite to that predicted by both the genetic-conflict and ovarian time-bomb hypotheses. Observations like these led Iwasa and Pomiankowski (1999) to propose that selection for different phenotypes in males and females – especially different sizes – could lead to imprinting.

These authors noted that changing the expression level of a paternally derived gene on the X chromosome would affect only female offspring. In contrast, alteration of expression at a maternally derived locus subject to dosage compensation (*see* Article 15, **Human X chromosome inactivation**, Volume 1) would have greater effects on male offspring. Hence, greater male size, common in mammalian species, could be achieved by maternally inactivating an X-linked growth inhibitor and/or paternally silencing a growth enhancer. These predictions are the opposite of those made by the genetic-conflict hypothesis (Spencer *et al*., 2004). Moreover, the sorts of loci that might be subject to imprinting under Iwasa and Pomiankowski's hypothesis is considerably greater: any loci affecting characters for which optimum male and female phenotypes differ could be imprinted. The paucity of clear examples of imprinted X-linked genes, therefore, could be seen as evidence against this suggestion.

Spencer *et al*. (2004) argued that the above ideas could be extended to autosomal loci underlying characters for which being more similar to one parent than the other is advantageous. For example, given that male mammals usually disperse further than females, genes important in local adaptation in a heterogeneous habitat might be preferentially expressed from the better-adapted maternal copies and hence subject to paternal inactivation. There are, however, no current examples of imprinting that support these latest ideas.

In summary, several hypotheses have been proposed to explain the paradox of imprinting – the apparently disadvantageous functional haploidy at imprinted loci – but not one explains all the observations. Some suggestions not discussed here (e.g., better control of gene expression) have little support, either empirical or theoretical, but three hypotheses – ovarian time bomb, genetic conflict, and differential selection on males and females – appear to do far better in plausibly explaining many known observations.

Short Specialist Review

Rapidly evolving imprinted loci

Joomyeong Kim and Lisa Stubbs
Lawrence Livermore National Laboratory, Livermore, CA, USA

Most mammalian genes have evolved within the boundaries of functional constraints, which preserve their protein-coding capability and proper temporal and spatial expression patterns. Such constraints clearly have operated on most imprinted genes since most are highly conserved in structure and function (*see* Article 37, **Evolution of genomic imprinting in mammals**, Volume 1). However, some imprinted loci have evolved in very unusual ways, diverging significantly in protein-coding capabilities and gene expression patterns. One of the most dramatic cases includes a cluster of imprinted genes located in human chromosome 19q13.4 and the homologous region of proximal mouse chromosome 7 (Figure 1). Six imprinted genes are located within this domain, including paternally expressed genes, *Peg3, Usp29*, and *Zfp264*, and maternally expressed loci, *Zim1, Zim2*, and *Zim3* (Kim *et al*., 1997; Kim *et al*., 1999; Kim *et al*., 2000a,b; Kim *et al*., 2001; Kuroiwa *et al*., 1996). Three-way comparisons of sequence from human, mouse, and cow have revealed an unusual degree of evolutionary change in this domain (Kim *et al*., 2003; Kim *et al*., 2004). Even the genes that remain intact and are similarly imprinted in human and mouse appear to be evolving rapidly, showing significant differences in domain structure or in protein-coding sequence. The rapid pace of evolution that characterizes this gene cluster is unprecedented for imprinted domains, and may provide a new paradigm for mammalian gene evolution.

The most striking change that has occurred in this domain is the loss of protein-coding capacity in three of the six imprinted rodent loci, *Zim2*, *Zim3*, and *Zfp264*, which are intact genes in human and cow. All three genes have maintained transcriptional activity in rodents and are still clearly imprinted, suggesting adaptation to unknown functions. One of these genes, *Zim3*, produces an RNA species in mice and rats that serves as an antisense transcript gene for the neighboring gene, *Usp29*. Noncoding RNA genes and antisense transcripts are common features of imprinted domains (Sleutels *et al*., 2000; Ogawa and Lee, 2002), but rodent *Zim3* may be the first case where the origin of antisense transcript genes can be traced unequivocally. Another feature that is unique to the *Peg3*-containing domain is that several homologous human and mouse genes have evolved very different genomic structures. For example, in mouse and cow, *Peg3* and *Zim2* represent two separate genes with distinct sets of exons and independent promoters, but in human these two genes share seven small exons and are transcribed from a common promoter. *Zim2* and *Peg3* each possesses

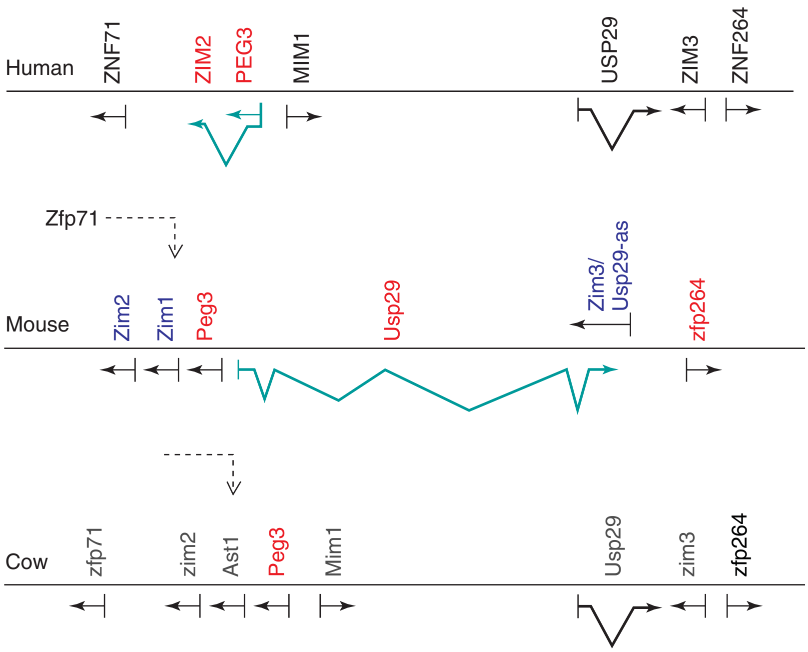

Figure 1 Comparative map of the Peg3-imprinted domain. The genomic organization of six imprinted genes in the Peg3 domain in three different mammals. Maternally expressed genes are marked in blue, whereas names of paternally expressed genes are shown in red. The genes with unknown imprinting status are marked in black. The imprinting status of cow *Zim2* and *Ast1* (Artiodactyls-specific transcript 1; Kim *et al*., 2004) are shown to be biallelic at adult testis, but the imprinting status at the other tissues is currently unknown. Lineage-specific changes have been observed in the downstream regions of *Peg3*. In human and cow, *ZNF71* is localized immediate downstream of *ZIM2*, whereas in mouse *Zim1*, a potential homolog or paralog of *ZNF71* has been moved to between *Peg3* and *Zim2*. A similar genomic insertion is also predicted to have happened in cow, the insertion of *Ast1* between *Peg3* and *Zim2*. These genomic rearrangements are marked as dotted arrows

the canonical structure of independent SCAN box–containing zinc-finger genes; together with the observation that the two loci are independently transcribed in mouse and cow, this fact has prompted the speculation that two originally separate genes merged to generate the transcription unit found in the primate lineage (Kim *et al*., 2004). Exon structure and promoter choice also differ significantly for human and mouse versions of the ubiquitin-specific protease gene, *Usp29*. In mouse, *Usp29* transcription starts from a shared bidirectional promoter at a site located ~150 bp from the start of *Peg3*, and the transcript is composed of seven exons distributed over more than 300 kb. In humans, however, transcripts arising from the same promoter region and containing sequences that correspond to the first two exons of mouse *Usp29* constitute parts of a novel untranslated human transcript, called *MIM1* (Mer-repeat containing imprinted transcript 1). The remaining five exons comprise the protein-coding transcript of the human gene, which is generated from an alternative downstream promoter. As a consequence, the expression patterns of human and mouse *Usp29* genes differ substantially; mouse

Usp29 is widely expressed with highest levels of transcription in the brain, whereas the human gene is testis-specific (Kim *et al*., 2000b). Preliminary data suggest that the exon structure of bovine *Usp29* is similar to that of the human gene. This suggests that the exon structure of mouse *Usp29* is a more neomorphic form than that of human and cow, and that *Mim1* and *Usp29* transcription units might have been fused to form a single large gene in the rodent lineage. Therefore, although in overall arrangement and content of genes, the *Peg3*-containing domain is well conserved among different mammals, the different genomic structures, promoter usage, and the shifting relationships between neighboring genes make this region unique among the known imprinted domains.

Why is this domain so unusual? The unique evolutionary patterns observed for genes within the *Peg3*-containing imprinted domain may be related to underlying features of the resident genes. The first feature is the relatively recent origin of most of the genes. Most of the known imprinted genes are ancient and highly conserved; for example, clear orthologs of *Igf2, Igf2r, and Peg1* are found in nonmammalian vertebrates such as fish and chickens (Nolan *et al*., 2001; Yang, S. K. and Chung, J. H., personal communication). By contrast, all genes in the *Peg3*-containing domain except *Usp29* are Krüppel-type zinc-finger (ZNF) genes, members of one of the largest and most evolutionarily dynamic mammalian gene families. In *Peg3* and *Zim2*, the DNA-binding ZNF region is attached to a SCAN effecter domain; *Zim1, Zim3,* and *Zfp264* belong to a second subclass containing a *Kruppel*-associated box, or KRAB effecter motif. SCAN- and KRAB-ZNFs are found only in amphibian, avian, and mammalian genomes, indicating the recent advent of these gene families. KRAB-ZNF genes, in particular, have expanded dramatically in mammalian lineages through repeated rounds of gene duplication (Hamilton *et al*., 2003; Huntley *et al*., 2004). Although the imprinted *Zim1/ZNF71*, *Zim2*, and *Zim3* genes encode relatively unique proteins, distantly related ZNF loci surround the imprinted domain in both human and mouse and these may provide some level of functional redundancy. Such redundancy may have reduced the otherwise potentially devastating effects of gene loss, resulting in the rapid loss of protein-coding capability of three mouse imprinted genes, *Zim2*, *Zim3*, and *Zfp264*.

Why have the imprinted genes maintained their transcriptional activity and imprinted regulation over the long evolutionary period since their coding sequence was inactivated? This may be related to the regulatory mechanisms that underlie genomic imprinting. A relatively large fraction of the transcripts produced within imprinted domains are expressed without the protein-coding capability, and many of these serve as antisense transcripts that are oppositely imprinted relative to the neighboring protein-coding genes (Sleutels *et al*., 2000; Ogawa and Lee, 2002). Some of these transcripts are unusually large, up to several hundred kilobases in length, as illustrated by the *Air* transcript (Lyle *et al*., 2000). In fact, large genes, such as *Usp29*, *Kcnq1*, *Snurp/Snurf*, and *Gnas,* are frequently found in imprinted domains. The prevalence of large transcription units, whether coding or not, may provide a hint that transcription per se may be required for establishing and/or maintaining specific types of chromatin structure in imprinted domains. This is consistent with the current view that many untranslated mammalian transcripts may have regulatory roles for chromatin structure and neighboring genes

(Kiyosawa *et al*., 2003; Tufarelli *et al*., 2003). The potential role of transcription itself for imprinted regulation may possibly help explain why the imprinted pseudogenes in the *Peg3*-containing domain have maintained transcriptional activity without protein-coding capability. The prevalence of long-distance transcription in imprinted domains might also have been a trigger for unusual gene fusion events that have been observed in the *Peg3*-containing region, *PEG3/ZIM2* in human and possibly *Usp29/Mim1* in mouse (Figure 1).

Evolutionary changes in sequence, imprinting status, and coding capacity have been demonstrated for a handful of other imprinted genes (Chai *et al*., 2003; Hitchins *et al*., 2001). However, the high level of evolutionary plasticity observed in the *Peg3* region has not been seen in the other known imprinted domains. In contrast to the genes in the human chromosome 19–imprinted domain, the other well-known imprinted loci were established, and embedded in well conserved pathways of development and behavior, long before the advent of imprinted regulation arose in mammals. In contrast, we predict that *Peg3* and its imprinted neighbors arose around the time that genomic imprinting began as a mechanism for gene regulation. This recent evolutionary history is likely to be one reason why the imprinted genes in the *Peg3*-containing domain appear to have evolved so rapidly and to have diverged in such a lineage-specific fashion. Dissecting the activities and developmental roles of the genes in this domain will be challenging due to the differences between humans and mice, since the mouse is the experimental system of choice for mammalian gene function and imprinting studies. However, the predicted roles of *Zim1, Zim2, Zim3, Znf264,* and possibly *Peg3* as transcriptional regulators suggest the impact of genomic imprinting on a wider network of mammalian genes. Studying the impact of their conservation and loss will provide a unique window to the evolution and functions of mammalian imprinted domains.

Short Specialist Review

Imprinting and behavior

James P. Curley and Eric B. Keverne
University of Cambridge, Madingley, UK

1. Evidence for the role of imprinted genes in behavioral phenotypes

The crossbreeding of animal species with one another can often produce hybrids with parent-of-origin-specific changes in behavioral phenotypes. For instance, the offspring of a male zebra and a female donkey are noted for their stubbornness in comparison with the reciprocal cross (Gray 1972; Walton & Hammond 1938). For many years, it was unclear why these genetically equivalent individuals behaved in consistently different ways dependent upon parent of origin. Following the discovery of genomic imprinting, it is now acknowledged that these offspring differ in their expression of imprinted genes and that differences in the maternal and paternal alleles of reciprocal crosses at these loci could lead to the observed behavioral differences.

Hybrid F1 mice produced from mating a male from an inbred strain A and a female from inbred strain B can be compared with those produced from the reciprocal cross. If both sets of offspring are transferred as embryos into a different strain C, these offspring are genetically equivalent in every respect with the exception of their imprinted genes. Interestingly, it was found that reciprocal cross F1 offspring avoid female urine from their maternal strain and investigate more the urine from an unrelated strain D in a choice test (Isles *et al*., 2001). However, no preference was observed when these mice were given the opportunity to investigate female urine from either a neutral strain D or their genetic paternal strain. This finding has been replicated with at least two separate parental sets of inbred strains, demonstrating that the effect of imprinted genes on mate choice is likely to be universal and not an epiphenomenon of one particular inbred strain (Isles *et al*., 2002). Moreover, since the F1 offspring were embryo transferred to foster mothers of a separate strain, this eliminated the possibility that the avoidance of maternal strain odors was dependent upon any learning during pup development.

The importance of genomic imprinting in brain and behavioral development was further illustrated by identifying where in the brain cells expressing imprinted genes preferentially develop (Allen *et al*., 1995; Keverne *et al*., 1996a). Mice with two complete sets of maternal or paternal chromosomes were only viable until day 10 of gestation (*see* Article 28, **Imprinting and epigenetics in mouse models and embryogenesis: understanding the requirement for both parental**

genomes, Volume 1). However, this lethal phenotype could be rescued by producing chimeric mice that possess a mixture of genetically normal cells together with cells containing two copies of maternal chromosomes (parthenogenomes, Pg) or two copies of paternal chromosomes (androgenomes, Ag). Those mice that received a contribution of paternally disomic cells had smaller brains, but with localized distribution of Ag cells to the ventral limbic forebrain. Conversely, those mice with a higher contribution of maternally disomic cells had larger brains, with localized distribution of Pg cells in cortical structures and the striatum but with virtual absence of these cells in the hypothalamus. Interestingly, male Pg mice were more aggressive than control mice, being quicker to attack an opponent male (Allen *et al*., 1995). However, no direct link between specific imprinted genes and this behavior has yet been discovered.

More recent research has looked for specific imprinted genes and investigated their expression patterns in different tissues. Currently, nearly a hundred imprinted genes have been identified, many of which are expressed in the brain and have immediate significance for behavioral functioning. One obvious example is the maternally specific expression of the serotonin receptor 2A gene (*Htr2*) in both humans and mice (Kato *et al*., 1998; Kato *et al*., 1996). Three other genes, *Gnas* (a G protein involved in cell signaling), *Nesp* (a splice variant of *Gnas*), and *Nnat* (a brain specific transmembrane protein), that are all expressed in the brain have been put forward as candidate genes for the reciprocal activity phenotype observed in mice with uniparental disomies (UPDs, *see* Article 46, **UPD in human and mouse and role in identification of imprinted loci**, Volume 1) of chromosome 2 (Cattanach & Kirk 1985; Isles & Wilkinson 2000). In this instance, offspring with a partial maternal or paternal UPD are hypokinetic or hyperkinetic respectively.

In humans, the importance of imprinted gene expression in the brain has been recognized from behavioral disorders (*see* Article 26, **Imprinting and epigenetic inheritance in human disease**, Volume 1). Of major interest is a cluster of maternally and paternally imprinted loci on human chromosome 15q11-q13, which is homologous to a region on mouse chromosome 7 (Yang *et al*., 1998). Paternal and maternal deletions of this chromosomal region are associated with Prader–Willi Syndrome (symptoms include mild mental retardation and hyperphagia) and Angelman Syndrome (symptoms include mental retardation, absent speech and inappropriate tongue movements, and laughter) respectively (Nicholls & Knepper 2001). Several candidate-imprinted genes have been identified in this area including the paternally expressed *ZNF127*, *NECDIN*, and *IPW* and the maternally expressed *UBE3A*. These chromosome 15 imprinting disorders have been associated with malfunctioning chromosomal regions, but a mutation in the imprinting mechanism could also affect neighboring nonimprinted genes such as those coding for subunits of the $GABA_A$-receptor (DeLorey *et al*., 1998). Parent-of-origin effects on the inheritance of several other behavioral disorders including autism, schizophrenia, and bipolar affective disorder have also been reported (Isles & Wilkinson 2000), although candidate-imprinted genes have yet to be identified.

Most studies of imprinted genes are phenotype led and provide for the possibility of a role for imprinted genes in the regulation of behavior, but few link specific genes with specific phenotypes. However, recent studies using modern molecular genetic techniques to target specific imprinted genes have resulted in the

development of behavioral phenotypes. For instance, mice with a targeted mutation of the paternally expressed *Grf1* (involved in Ras signaling) have impaired long-term emotional memories (Brambilla *et al.*, 1997). Learning and memory deficits, in addition to motor dysfunctions and inducible seizures have been identified in mice lacking the putatively paternally expressed *Gabrb3* gene (codes for a $GABA_A$-receptor subunit) and the maternally expressed *Ube3a* gene (codes for E6-AP ubiquitin protein ligase).

In addition to the effects of these genes on cognitive behavior, the role of paternally expressed genes on maternal and infant behavior has been studied using mice carrying a targeted mutation of either the *Mest/Peg1* or the *Peg3* gene (Curley *et al.*, 2004; Lefebvre *et al.*, 1998; Li *et al.*, 1999). The unique inheritance pattern of paternally expressed genes enables the effect of the mutation on maternal and infant behavior to be studied independently. Females carrying the mutation give birth to wild-type offspring when mated with a wild-type male, whereas wild-type females give birth to offspring carrying the mutation when mated with a homozygous mutant male. When female mice carry a mutation in one of these two paternally expressed genes, they are impaired in a whole suite of maternally related functions and their offspring are growth retarded during both the prenatal and postnatal periods (Keverne 2001). They are slower to retrieve pups, build nests, and crouch over pups, and their resting body temperature is lower than that of the wild-type females, making it difficult to keep the pups warm. During pregnancy, mutant females consume less food than wild-type controls, and hence their wild-type embryos are weight retarded. After birth, mutant females are impaired in their letdown of milk from mammary glands, resulting in their wild-type offspring failing to suckle adequate milk and thereby suffering further growth retardation, leading to delayed puberty. In addition to these behavioral deficits, females carrying the *Mest/Peg1* mutation also do not show placentophagia. Mechanistically, the decreased maternal behavior associated with females carrying the *Peg3* mutation has been associated with a significant decrease in oxytocin positive neurons in the paraventricular nucleus of the hypothalamus immediately postpartum. Female mammals are reliant on a surge of oxytocin following birth to activate maternal behavior as well as milk letdown, and it appears that female mutant mice fail in this respect.

Genomic imprinting appears to have evolved approximately 150 million years ago in the ancestor of eutherian (placental) and marsupial mammals (John & Surani 2000). One favored hypothesis for its evolution is the conflict theory (Burt & Trivers 1998; Haig & Graham 1991), which argues that in promiscuous species paternally expressed genes promote offspring growth, even at the expense of the mother's future fitness, while maternally expressed genes counteract this by suppressing offspring growth. Most of the early empirical work supported this hypothesis; imprinted genes were found to be expressed in the placenta – the battleground for this parental tug-of-war – and maternal and paternal alleles were generally growth suppressing and promoting respectively. However, the expression of imprinted genes in the brain and their involvement in behavioral phenotypes cannot be intuitively explained in terms of parental conflict. Indeed, instead of being driven by conflict, the expression of paternally expressed genes in the maternal and

infant brain may have evolved through coadaptation for the same genes *Mest/Peg1* and *Peg3* that ensure that infant growth and survival are also essential for good nurturing behavior (Curley *et al*., 2004; Keverne 2001). Overall, imprinted genes expressed in the brain appear to be important in the regulation of brain development and, interestingly, may have been crucial to the remodeling of brain structures during mammalian evolution (Allen *et al*., 1995; Keverne 2001; Keverne *et al*., 1996b).

Short Specialist Review

Spreading of X-chromosome inactivation

Jason O. Brant and Thomas P. Yang
University of Florida College of Medicine, Gainesville, FL, USA

During early female mammalian embryogenesis, one of the two X chromosomes is randomly inactivated in each cell of the embryo (*see* Article 28, **Imprinting and epigenetics in mouse models and embryogenesis: understanding the requirement for both parental genomes**, Volume 1 and Article 41, **Initiation of X-chromosome inactivation**, Volume 1). The stable inactivation of genes on one of the two X chromosomes in females functionally equalizes the apparent dosage imbalance of X-linked genes between males and females (Lyon, 1961). This process of X-chromosome inactivation (XCI) is believed to occur in three steps: initiation (Lyon, 1961; Russell, 1963), spreading (Russell, 1963), and maintenance (Barr and Carr, 1962). Initiation of XCI is believed to occur in the X inactivation center (XIC) and involve the *XIST* (inactive X specific transcript) gene, which is located within the XIC (in Xq13 in humans). The *XIST* gene encodes a 17-kb noncoding transcript that is expressed exclusively from the inactive X chromosome (Xi) (Brown *et al*., 1992), localized to the nucleus, accumulates at the Xi (Brown *et al*., 1992), and is required for XCI (Penny *et al*., 1996). Once XCI is initiated, the inactivation process is believed to spread bidirectionally in cis from the XIC along the length of the X chromosome. In all subsequent somatic cell divisions, the inactive state of the same Xi is maintained in each daughter cell, ensuring that the pattern of XCI is heritably and stably maintained throughout the life of the organism. However, XCI does not occur uniformly along the entire length of the X chromosome because numerous domains and loci have been shown to partially or completely escape inactivation (Schneider-Gadicke *et al*., 1989; Carrel and Willard, 1999; Disteche, 1999; Tsuchiya *et al*., 2004).

The molecular mechanism by which inactivation spreads bidirectionally from the XIC along the length of the X chromosome, yet appears to "skip" over domains that escape inactivation, remains perhaps the least understood aspect of X-chromosome inactivation. The fact that the spreading of inactivation occurs during a narrow interval in early female development among a relatively small number of cells has hampered studies to examine the mechanisms involved in this phase of XCI.

One of the early observations of XCI in mice was that in X;autosome translocations, inactivation of genes on the Xi appeared capable of spreading into the adjacent autosomal chromosome (Russell, 1963). Using coat-color variegation as

a marker of autosomal gene silencing, it was shown that these translocations could result in variable and discontinuous spreading of inactivation into autosomal chromatin. The extent of spreading of inactivation into the adjacent autosomal regions was variable, depending upon the location of the translocation breakpoints, including the breakpoint on the X. This apparent spreading of gene silencing into autosomal regions from the Xi suggested that spreading of inactivation along the X chromosome might be an integral feature of the process of XCI.

Similar indications of spreading of silencing into adjacent autosomal regions have also been observed on the human X chromosome in human X;autosome translocations (Canun *et al*., 1998; White *et al*., 1998; Sharp *et al*., 2001; Sharp *et al*., 2002). Patients with X;autosome translocations can present with variable phenotypic severity, suggesting variable extent of spreading of inactivation into the translocated autosomal regions, which is dependent on the location of the translocation breakpoints. This has included patients with unbalanced X;autosome translocations who showed phenotypes less severe than the corresponding autosomal trisomy. For example, a high-resolution molecular analysis of the spread of inactivation into autosomal DNA was performed in a patient with an X;4q translocation (White *et al*., 1998). 4q duplications are usually associated with dysmorphic features and severe growth and mental retardation. However, this patient presented with a normal phenotype, suggesting spread of inactivation into the translocated 4q chromosome. RT-PCR was performed for 20 transcribed sequences spanning this 4q translocation; results showed that gene silencing had spread into the translocated autosomal chromatin, though 30% of the sequences examined escaped inactivation. These data, along with similar observations of the spreading of silencing in other X;autosome translocations (Canun *et al*., 1998; White *et al*., 1998; Sharp *et al*., 2002), further suggested that autosomal DNA might lack X chromosome–specific characteristics and/or sequences that allow efficient response to the signal for XCI and/or the maintenance of inactivation. The fact that X inactivation is capable of spreading into autosomal DNA in X;autosome translocations in a discontinuous and variable fashion suggested reduced efficiency of spreading into autosomal chromatin.

The apparent ability of XCI to spread along the length of the X chromosome suggested there must be something unique about the X chromosome that promotes an efficient response to inactivation and facilitates the efficient spreading of inactivation along the length of the chromosome. The Riggs "way station" model proposed the presence of DNA elements along the X chromosome that function as way stations or "boosters" to promote or enhance the spreading of inactivation (Riggs *et al*., 1985). This model was later expanded upon by suggesting that these way stations were somehow uniquely arranged on the X chromosome in a manner that facilitates the efficient spreading of inactivation along the length of the X chromosome (Riggs, 1990).

The identity of the proposed way station elements on the X chromosome has proved elusive. Lyon (1998) proposed long interspersed repetitive elements (LINE-1; L1) elements as potential candidates for the way station elements hypothesized in the original Riggs model. Evidence in support of a role for L1, and perhaps other repetitive elements, in spreading of XCI has remained circumstantial, but increasingly compelling. For L1 elements to function as way stations to

facilitate spreading of XCI, the X chromosome would be expected to be enriched in these elements as compared to autosomal DNA, and regions of autosomal DNA into which XCI more readily spreads in X;autosome translocations should also be enriched in L1 elements. Consistent with these expectations, Lyon showed a strong correlation between the spread of inactivation into autosomal regions and the density of L1 elements in these regions by analyzing previously characterized X;autosome translocations (Lyon, 1998). Additionally, when an *Xist* transgene was ectopically expressed on mouse chromosome 12 (Lee and Jaenisch, 1997), the spread of silencing was observed along the chromosome, but it was noted that the distal portion of the transgenic chromosome 12 lacked histone H4 hypoacetylation (histone H4 hypoacetylation is commonly associated with transcriptionally silent chromatin), suggesting that genes in this region may have escaped inactivation (Lee and Jaenisch, 1997). Fluorescence in situ hybridization (FISH) mapping of LINE elements on mouse chromosome 12 indicated a distinct lack of these repetitive elements in this distal region (Boyle *et al*., 1990), which Lyon proposed may explain the lack of the spread of silencing into this region. This again suggested that silencing spreads more efficiently in regions that are enriched in L1 elements rather than in regions where these elements are underrepresented (Lyon, 1998).

More recently, Bailey *et al*. (2000) investigated the distribution of L1 elements along the length of the entire X chromosome and compared this pattern to L1 distribution in human autosomes. Their findings showed that L1 elements are indeed enriched on the X chromosome by nearly twofold as compared to autosomal DNA, as would be expected according to Lyon's proposed role for L1 elements in spreading of XCI. Moreover, there was a nonrandom distribution of L1 elements on the X chromosome, with enrichment in the region of the XIC as Riggs had postulated earlier (Riggs, 1990). Furthermore, a significant decrease in the number of L1 elements was observed for regions of the Xi that escape inactivation, consistent with Lyon's proposed role for L1 elements in the spreading of XCI.

A detailed examination of a domain that escapes X inactivation in humans and the syntenic region in the mouse provided evidence, suggesting that other interspersed repetitive elements may also play a role in spreading of XCI (Tsuchiya *et al*., 2004). Sequence analysis of human Xp11.2 containing a domain of multiple genes that escape XCI, as well as the syntenic region of the mouse X chromosome, only showed a correlation between escape from XCI and the density of L1 repeats in the region of the *SMCX/Smcx* gene. No correlation between L1 repeat density and inactivation was noted for the remainder of the domain in humans where other genes also escape inactivation. However, a correlation was noted between long terminal repeat (LTR) density and the transcriptional status of genes in the domain that escape inactivation. The entire Xp11.2 domain that escapes inactivation in humans was noted to be reduced in LTR density, as compared to the whole X chromosome. Furthermore, in the syntenic region of the mouse, only the region containing the *Smcx* gene (which is the only gene in this region that escapes inactivation) was reduced in LTR density. These findings are consistent with a correlation between LTR density and the ability of genes to escape inactivation, and suggest that spreading of XCI may also be facilitated by LTR elements in addition to L1 elements (Tsuchiya *et al*., 2004).

Another element potentially involved in the mechanism for spreading of XCI is the *XIST* gene and its RNA product. The discovery and characterization of this unique transcript led to its emergence as a candidate to mediate the spread of X inactivation via association with the postulated way stations. Introduction of an inducible *Xist* transgene into an autosomal chromosome in male mouse embryonic stem (ES) cells demonstrated that expression of *Xist* RNA was required in cis for the spread of inactivation to occur in the flanking autosomal region (Wutz and Jaenisch, 2000). Although the expression of *XIST* RNA seems to be the first observable event leading to the spreading of inactivation, the mechanism by which the spread of inactivation occurs only in cis, how silencing is induced, and the identity of proteins or protein complexes that associate with *XIST* RNA are currently unknown. Although the precise role of *XIST* RNA in the spreading of XCI remains unclear, models of how *XIST* RNA may mediate spreading have been suggested on the basis of current knowledge of XCI and the Xi. Wutz *et al*. (2002) have suggested that there may be multiple low-affinity-binding motifs present on *Xist* RNA that could bind sites along the Xi in a cooperative manner, adding to stability of the chromatin-bound *Xist* RNA and leading to subsequent binding and accumulation of *Xist* RNA on adjacent chromatin sites, thereby facilitating the spreading of XCI. Previous studies have shown that *Xist* RNA that does not localize to chromatin is unstable and quickly degraded (Wutz *et al*., 2002), which may explain why the spreading of *Xist* RNA occurs only in cis. Lyon has proposed a role for *XIST* RNA in spreading of XCI that involves its interaction with L1 elements and subsequent inactivation via repeat-induced silencing (Lyon, 1998).

Repeat-induced silencing via an RNAi-mediated process has been postulated as a potential mechanism involved in XCI. Nascent L1, or other repetitive sequence transcripts, could induce silencing through the RNAi pathway (Hansen, 2003), similar to the heterochromatic silencing demonstrated in fission yeast (Verdel *et al*., 2004). In fission yeast, double-stranded (ds) RNA generated from transcription of centromeric repeats is processed by the RNAi machinery (Verdel *et al*., 2004). The processed siRNA is targeted to the site of transcription through sequence-specific interactions between the siRNA and chromosomal DNA, leading to recruitment of chromatin-modifying proteins such as SWI6 (Verdel *et al*., 2004). SWI6, the yeast ortholog of metazoan heterochromatin binding protein-1 (HP1), appears to facilitate the spread of heterochromatin formation in yeast (Schramke and Allshire, 2003). SWI6 binds to histone H3 methylated at lysine 9 (H3meK9), which leads to the formation of a silent chromatin nucleation center, which can then facilitate the spreading of silent chromatin (Schramke and Allshire, 2003). It is conceivable that similar mechanisms of HP1-mediated spreading of heterochromatin could also contribute to the spreading of silencing in XCI. Chadwick *et al*. have also drawn parallels between heterochromatin formation in yeast and mammalian X-chromosome silencing, in which HP1 recognizes methylated H3K9, and acts to promote the formation of heterochromatin and spreading of X inactivation (Chadwick and Willard, 2003).

Another possible mechanism that could facilitate spreading of XCI has recently been demonstrated for the autosomal mouse *Dntt* gene (Su *et al*., 2004). Analysis of histone modifications in the region surrounding the *Dntt* promoter in immature thymocytes showed that local changes in histone modifications at the promoter

could subsequently spread. Upon differentiation of immature thymocytes, where the *Dntt* gene undergoes functional silencing, deacetylation of H3K9 was observed near the *Dntt* promoter, which then spread bidirectionally throughout the locus. These results suggest that certain histone modification patterns associated with silent chromatin are capable of spreading bidirectionally from a nucleation site, a process that could conceivably be involved in the spreading of histone modification patterns associated with silent chromatin on the Xi following initiation of XCI at the inactivation center. Additionally, methylation of H3K27 and assembly of polycomb group (PcG) protein complexes on the Xi also appear to be involved in the process of initiation and establishment of inactivation (Plath *et al*., 2004).

The ability of XCI to spread along the length of the X chromosome, yet apparently skip over regions that escape inactivation, has proved problematic in regard to understanding the mechanism of spreading. As many as 15–20% of genes on the human Xi may escape inactivation to some degree (Carrel *et al*., 1999), and these genes that escape inactivation tend to localize in clusters and domains (Carrel *et al*., 1999). Thus, how does the signal that propagates spreading of XCI act discontinuously by skipping over domains as large as 235 kb, and then continue the spreading of inactivation downstream of these domains? This question may be explained by analysis of the X-linked mouse *Smcx* gene (Lingenfelter *et al*., 1998). Allele-specific expression patterns of the *Smcx* gene were examined at various time points throughout female development using RT-PCR. The results showed that *Smcx* is subject to complete inactivation during the initial silencing of the X chromosome in early female embryogenesis, but subsequently becomes reactivated, presumably though a progressive loss of maintenance of the inactive epigenetic state. This would suggest that XCI in fact spreads uniformly along the Xi in early embryogenesis, then certain loci and domains fail to maintain the transcriptionally silent state and become reactivated later in development.

XCI poses a variety of unusual mechanistic challenges to female mammalian cells, including the problem of how to heritably silence genes on one of two essentially identical X chromosomes within the same nucleus, and how to spread inactivation in cis from the XIC along the length of the X chromosome. Although some or all of the DNA sequences (e.g., L1 elements), factors (e.g., *XIST* RNA), and mechanisms (e.g., RNA-mediated gene silencing) described may be involved in the mechanisms responsible for spreading of XCI, a clear understanding of the process by which XCI inactivation spreads in cis along the X chromosome remains to be determined. The process by which this occurs, while becoming clearer, stills remains mechanistically elusive, as the potential binding partners of *XIST* RNA and other factors recruited to mediate the silencing of genes on the Xi have yet to be identified. As more protein complexes are identified that associate with the Xi, we may begin to gain a better understanding of the mechanisms involved in spreading of XCI.

Short Specialist Review

Initiation of X-chromosome inactivation

Lygia V. Pereira and Raquel Stabellini
Universidade de São Paulo, São Paulo, Brazil

Dosage compensation is the process by which the amount of X-linked gene products between individuals with one and two X chromosomes is equalized (*see* Article 15, **Human X chromosome inactivation**, Volume 1). Currently, three different mechanisms of dosage compensation are known in nature (reviewed by Marin *et al*., 2000). In *Drosophila*, the single X chromosome in males has a twofold increased level of transcription when compared to each of the two X chromosomes in females. In contrast, in *Caenorhabditis elegans* (*C. elegans*), a twofold decrease in X-linked gene expression in hermaphrodites (XX) relative to males (XO) ensures equalization of X-linked gene expression.

In mammals, dosage compensation between XY males and XX females is achieved by the transcriptional silencing of one X chromosome in female somatic cells (Lyon, 1961), a process called X-chromosome inactivation (XCI). Therefore, while in *Drosophila* and *C. elegans*, the levels of gene expression from each X chromosome in the female or hermaphrodite, respectively, are indistinguishable, a formidable feature of the mechanism of dosage compensation in mammals is that female cells must differentiate the two X chromosomes, rendering only one transcriptionally active.

A snapshot of the inactive X (Xi) in somatic cells would show several epigenetic modifications of this chromosome when compared to the active X (Xa) (reviewed by Hall and Lawrence, 2003). The Xi is coated by RNA from the *Xist* gene expressed in cis. It presents higher degree of methylation of CpG islands, higher concentration of the histone variant macroH2A1, and association with the BRCA1 protein. In addition, the histones in the Xi have several posttranslational modifications associated with gene silencing, including hypoacethylation of histones H4, methylation of lysine 9 of histones H3 (H3K9), and dimethylation of lysine 4 of histones H3 (H3K4).

The issue is: how did the Xi get from its originally active state at the zygote to that state of inactivity during early embryonic development? This epigenetic transformation requires that the cell counts the number of X chromosome and chooses which X will be inactive and which will be active so that in a differentiated cell there will be only one Xa per diploid genome.

Counting X chromosomes requires that the cell somehow differentiates the X from the other chromosomes. The identity of the X chromosome is tightly linked

to the X-inactivation center (Xic), mapped at Xq13 in humans and in the syntenic region located in band D of the X in mice. Only when this minimal region of the X is present in an X:autosome translocation will the translocated chromosome be counted by the cell as an X to participate in XCI. To date, two genes within the Xic have been demonstrated to be involved in XCI: *Xist* (X inactive specific transcript), expressed exclusively from the Xi and required for initiation of XCI; and its antisense *Tsix*, which downregulates *Xist* in cis in undifferentiated cells.

The choice of which X to be inactive is made in two very different forms in the mouse embryo: in cells of the trophectoderm, the paternal X (Xp) is always chosen to be the Xi, whereas in the inner cell mass (ICM) the choice is random in each cell. Imprinted XCI in the trophectoderm has been associated with maternal imprinting of the *Tsix* gene. In that lineage, lack of *Tsix* expression from the Xp leads to stabilization of *Xist* RNA expressed in cis, triggering inactivation of that chromosome.

In the ICM, although generally either the Xp or Xm is randomly chosen to be inactive, the choice of the Xi may be influenced by the X-controlling element (Xce), located within the Xic. Stronger Xce alleles, which render the corresponding X more likely to remain active, have been described in mice. Mutation studies of the *Xist* and *Tsix* genes, also within the Xic, indicate a role for those also in choosing, for instance, a 65-kb deletion 3' of *Xist* including most of the *Tsix* gene leads to primary completely skewed inactivation of the mutant X. In addition, dominant mutations mapped to different mouse autosomes can disrupt normal random XCI. However, the mechanism of choice of the Xi in cells of the ICM is still unknown.

Once the future Xi is chosen, inactivation starts. Until recently, XCI was thought to initiate at cells of the trophectoderm, where the Xp is always inactivated. Subsequently, random XCI would take place in cells of the ICM, where in each cell either the maternal X (Xm) or the Xp is inactivated.

However, more recent studies have detected XCI as early as the cleavage states before cellular differentiation (Okamoto *et al*., 2004; Mak *et al*., 2004). At that stage, imprinted XCI takes place in all cells of the embryo, imposing sequential epigenetic modifications in the Xp (Figure 1). These modifications are triggered in cis by the expression of the *Xist* gene from the Xp. At the 4-cell stage, *Xist* RNA is first observed, coating the Xp; H3K4 hypomethylation and H3K9 hypoacetylation are detected at the 8-cell stage; at 16-cell stage, the Eed/Enx1 polycomb group complex and the histone variant macroH2A accumulate in the Xp; finally, at the early blastocyst stage, association of methylated H3K9 with the Xp takes place. Together, these epigenetic modifications of the Xp lead to its inactivation.

At the blastocyst stage, while cells of the trophectoderm and the primitive endoderm maintain the inactive state of the Xp, cells of the ICM reactivate this chromosome, erasing the epigenetic marks imposed during the imprinted XCI. Reversible XCI had been reported in embryonic stem (ES) cells carrying an inducible *Xist* transgene (Wutz and Jaenisch, 2000). In this important experimental model of initiation of XCI, expression of *Xist* before differentiation leads to *Xist*-dependent and reversible XCI. Similarly, in the ICM, loss of *Xist* expression from the Xp leads to dissociation of the Eed/Enx1 complex followed by loss of histone H3K9 and K27 methylation, so that at implantation, the Xp is reactivated.

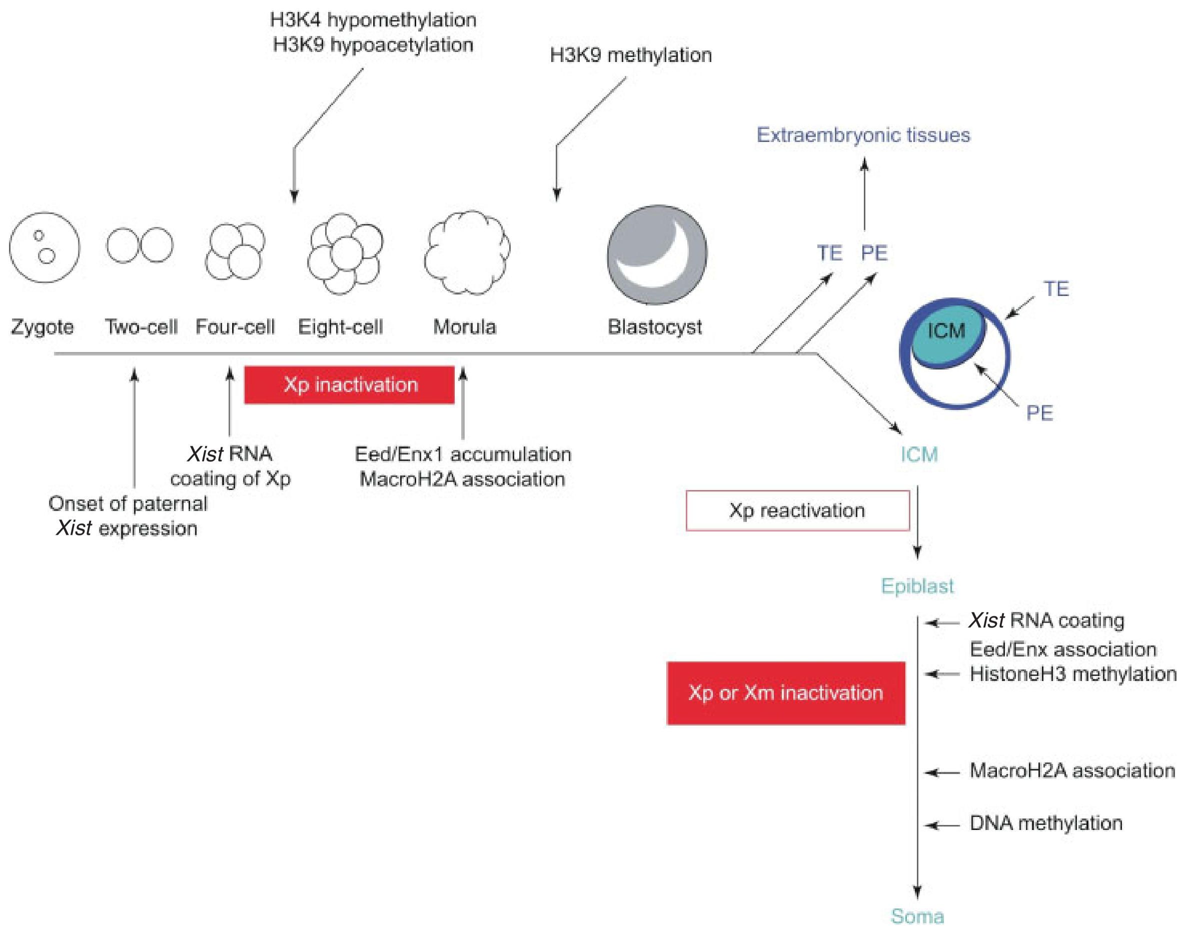

Figure 1 Kinetics of XCI during early mouse embryonic development. Imprinted inactivation of Xp established before cell differentiation is erased in the ICM. Random inactivation of either the Xp or Xm will then take place in cells of the epiblast (see text). PE, primitive ectoderm; TE, trophectoderm (Adapted from Heard E (2004) Recent advances in Z-chromosome inactivation. *Current opinion in Cell Biology*, **16**, 247–255, with permission from Elsevier)

At that point, a second round of XCI will take place in cells of the epiblast, starting with repression of *Tsix* in the future Xi, now chosen at random in each cell, and the consequential stabilization of *Xist* RNA in cis. The *Xist* RNA coating the future Xi recruits transiently the Eed/Enx1 complex required for methylation of histones H3, stabilizing the structure of the Xi chromatin. Further modifications of histones H4, recruitment of macroH2A, and methylation of CpG islands will lock that chromosome in an inactive state that is independent of *Xist* expression and heritable through mitosis.

XCI is traditionally thought of as a mechanism triggered by the presence of supernumerary Xs, involving counting the X chromosomes (or Xics) and randomly choosing the one to be inactivated. Alternatively, XCI can be looked at as a default mechanism in the mammalian cell: X chromosomes will be inactivated, unless they are somehow protected from inactivation. Therefore, the existence of a blocking or protective factor in the cell has been postulated, which must exist in very limited amounts, allowing protection from inactivation of only one X per diploid genome.

The affinity of the protective structure with an X, or with an Xic, may influence the probability of the corresponding X to remain active, that is, it may influence the choice of the Xa. Weaker Xce alleles may have a primary sequence with lower affinity with the protective structure, rendering the corresponding X unprotected from inactivation. Following that rationale, completely skewed inactivation of the X carrying the 65-kb *Tsix* deletion may be due to total inability of that chromosome to interact with the protective structure. One can also hypothesize that the autosomic factors influencing the choice of the Xi may be part of the protective structure, and therefore, identification of those factors may shed some light on the nature of that structure.

In the last few years, much has been learned about the nature and the dynamics of epigenetic modifications imposed in the Xi during XCI, particularly highlighting the role of posttranslational modifications of histones in defining the epigenetic state of the Xi (*see* Article 40, **Spreading of X-chromosome inactivation**, Volume 1). However, the mechanisms by which the female cell chooses and protects one X chromosome from inactivation and the players that impose those epigenetic modifications on the Xi remain obscure and a fascinating topic of research in modern biology.

Finally, it is important to notice that most, if not all, that is known about initiation of XCI comes from studies in the mouse, either in preimplantation embryos or in ES cells. Important differences between XCI in mouse and humans exist, including the apparent absence of a functional human *TSIX* gene, and of imprinted XCI in human extraembryonic tissues (reviewed by Vasques *et al*., 2002). Therefore, experimental systems for the study of XCI in humans must be developed. In that sense, the recent availability of human ES cell lines (Cowan *et al*., 2004) may allow the dissection of initiation of human XCI.

Short Specialist Review

Mechanisms of epigenetic loss of chromosomes in insects

Clara Goday and Maria-Fernanda Ruiz
Consejo Superior de Investigaciones Científicas, Centro de Investigaciones Biologicas, Madrid, Spain

1. Introduction

The programmed exclusion of chromosomes from the genome is a remarkable developmental phenomenon that in insects is very diversified between different families and between individual species. The best-known examples are found in Diptera such as *Sciara* (Sciaridae), *Heteropeza*, *Miastor*, *Mayetiola*, *Wachtiella* (Cecidomyiidae), *Acritocopus* (Chironomidae), and also in Homoptera coccids (reviewed in White, 1973). A common feature is that specific chromosomes are eliminated from presomatic cells at early cleavage divisions by the time of somatic/germ-line separation. In some species, there is an additional chromosome loss from germ cells. In all cases, this process leads to a reduction in the number of chromosomes in the somatic tissues compared to the germline.

Somatic embryonic elimination involves chromosomes of the regular complement (mostly sex chromosomes) and/or chromosomes that are restricted to germline. In both cases, the timing of chromosome elimination in early embryos is species specific. A classic example of sex chromosomes elimination is that of *Sciara* where the loss of one or two X chromosomes at early cleavages determines the sex of the embryo (Metz and Moses, 1926). That this type of elimination is preceded by imprinting was discovered in *Sciara* when it was found that the discarded X chromosomes are invariably of paternal origin (Crouse, 1960; reviewed in Gerbi, 1986). Despite its importance, the parent-of-origin-specific mark(s) involved in this elimination system is still unknown. A substantial number of examples, including cecidomyiids species, show elimination of sex chromosomes linked to sex determination (Nicklas, 1959; reviewed in White, 1973). An extreme case is found in coccids diaspididae where the somatic elimination of the entire paternal chromosome set produces solely male embryos (reviewed in White, 1973). On the other hand, germ-line-limited chromosomes, present in certain sciarids and most cecidomyiids and chironomids ("L", "E", or "K" chromosomes, respectively), are all discarded from the presumptive somatic nuclei at early cleavages in both sexes. This is independent of their number, which can be extremely high and varies greatly between species. In this respect, the elimination of germ-line-limited chromosomes

in early cleavages reduces the chromosome number in the future somatic nuclei to a level characteristic of the Diptera in general. This may be particularly important, since the developmental pattern in Diptera has been adjusted to a low number of chromosomes in relatively small nuclei (Nicklas, 1959). Most of the germ-line-limited chromosomes are of heterochromatic nature and contain repetitive DNA sequences. The functional role of these chromosomes in the germline remains obscure. However, experimental elimination of the E chromosomes in pole cells of cecidomyiids species revealed that their presence is necessary for the female gonad development (Geyer-Duszynska, 1959).

In germ cells, chromosome elimination commonly involves the loss of the whole paternal regular set of chromosomes during male meiosis. In *Sciara* species, an exceptional and unique type of paternal X-chromosome nuclear exclusion also takes place in embryonic germ cells of both sexes (reviewed in Goday and Esteban, 2001).

Despite many years of study, chromosome loss in insects is far from being exhaustively analyzed. An intriguing question is whether the cellular and molecular mechanisms underlying these processes share common traits between different insects. With this in mind, we discuss here relevant data coming from examples in Diptera, Sciaridae, Cecidomyiidae, and Chironomidae.

2. Mechanisms of chromosome elimination in the soma

In all species, chromosome loss at early embryonic mitotic divisions is produced by an abnormal segregation of the chromosomes. A regular cytological feature of this event is the occurrence of “lagging chromosomes” at anaphase, so that these chromosomes fail to enter the daughter nuclei.

In sciarids, as classically described for L- and X-chromosome elimination processes in *S. coprophila* (Dubois, 1933; reviewed in Gerbi, 1986), the chromosomes begin their movement toward the poles at anaphase but are incapable of complete chromatid separation and remain at the equatorial plate (see Figures 1 and 2). These early observations led to the proposal that alterations in centromeric activity cause chromosome loss in sciarids (reviewed in Gerbi, 1986). In *S. coprophila*, moreover, it was found that a cis-acting locus or *controlling element* (CE) located in a heterochromatic block near the centromere of the X chromosome regulates the elimination process (Crouse, 1960). The molecular nature of the CE is still undetermined, but when the CE is translocated to an autosome it is able to direct its elimination in paternally inherited translocations (Crouse, 1979). Recent analysis of L- and X-chromosome elimination kinetics in *S. coprophila* through confocal microscopy showed that the centromeres remain attached to the spindle and stretched toward the poles at anaphase, while the chromatids remain joined at a region on the long arm of the X chromosome (de Saint-Phalle and Sullivan, 1996). It was proposed that anaphase lag (of X and L chromosomes) is caused primarily by a CE-controlled failure of chromatid separation rather than by a CE-controlled centromere dysfunction (de Saint-Phalle and Sullivan, 1996). To find the specific biochemical alterations in the chromatid separation processes at the anaphase transition would be extremely interesting to further develop this conclusion.

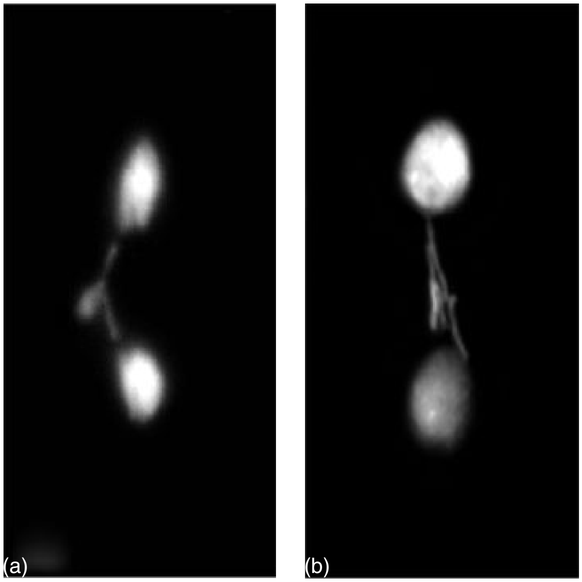

Figure 1 X-chromosome elimination from the soma in *S. ocellaris* embryos. DAPI-stained early syncitial somatic divisions. Lagging X chromosomes in somatic division undergoing elimination. Only one X chromosome is discarded from cells of female embryos (a), while two X chromosomes are discarded from cells of male embryos (b) (Reproduced by permission of John Wiley & Sons, Inc. from C. Goday and M. R. Esteban (2001) *BioEssays*, **23**, 242–250)

Another yet undiscovered issue is the nature of the cytoplasmic factor(s), produced by the mother and distributed within the egg, involved in regulating the number of X chromosomes eliminated in sciarids. As demonstrated in sciarid species, this factor(s) is produced in the oocyte during oogenesis (reviewed in Gerbi, 1986 and Goday and Esteban, 2001). Two main models have been put forward to explain the number of eliminated X chromosomes (de Saint-Phalle and Sullivan, 1996; Sánchez and Perondini, 1999). The one-factor model (de Saint-Phalle and Sullivan, 1996) is based on a maternal factor that regulates the differential X-chromosome elimination pattern through the quantity of this factor present in the egg. In the alternative, two-factor model (Sánchez and Perondini, 1999), a hypothetical chromosomal factor interacts with the X chromosome(s) causing its (their) elimination. In this model, the number of X chromosomes to be eliminated is controlled by a maternal factor that regulates the amount of free chromosomal factor interacting with the X chromosomes (reviewed in Goday and Esteban, 2001).

In contrast to Sciara, in the chironomid *Acritopus* during Ks-chromosomes elimination, the Ks sister chromatids are not stretched in the direction of the spindle poles, and their centromeres appear not to separate while somatic chromosomes move to the poles (Staiber, 2000). Since Ks chromosomes stay in the equatorial plate, it was concluded that their sister chromatids remain joined at their centromeric regions rather than at the chromosomes arms or the telomeres (see Figure 2). Moreover, it was proposed that proteins responsible for centromeric cohesion might be involved in this type of chromosome behavior (Staiber, 2000).

		Cytological events (anaphase)	Proposed elimination mechanisms
Sciaridae		Incomplete anaphasic movement of chromosomes	Failure of sister chromatid separation at chromosomes arms
Chironomidae		Lack of anaphasic movement of chromosomes	Failure of sister chromatid separation at centromeric regions
Cecidomyiidae		Aberrant anaphasic movement of chromosomes	Alterations in centromere kinetic activity

Figure 2 Chromosome elimination in embryonic somatic cells. Diagram summarizing the“lagging chromosomes” phenotypes, relevant cytological events, and proposed elimination mechanisms. E denotes the chromosomes undergoing elimination

Interestingly, a specific highly repetitive DNA family located in the paracentromeric heterochromatin of the Ks chromosomes was identified in *A. lucidus* (Staiber *et al*., 1977). Whether these repetitive DNA sequences are involved in identifying the eliminating chromosomes as proposed (Staiber *et al*., 1977) remains unknown.

The elimination of E chromosomes in cecidomyiids displays varied chromosome-lagging patterns (see Figure 2). In examples of *Miastor*, *Micophila,* and *Heteropeza*, E chromosomes remain at the equator as a result of the apparent absence or diminution of the usual mid-anaphase tension (Nicklas, 1959; Nicklas, 1960; White, 1973). In several of the observations, it is clear that among the chromosomes to be lost there are chromatid pairs that remain totally separate and yet fail to exhibit normal mid-anaphase movement. In *Mayetiola* and *Wachtliella* examples, all E chromatids separate completely but fail to continue anaphase along with S chromosomes (Geyer-Duszynska, 1959; reviewed in White, 1973). A remarkable case is that of *Heteropeza pygmaea* where until mid-anaphase both the E and S chromosomes segregate to the poles as in a normal cleavage division. Time-lapse cinémicrography revealed that the velocity of the E chromosomes, however, is less than that of the S chromosomes. After variable amounts of anaphase movements, the E chromosomes return toward the equator with their kinetochores being still oriented toward the poles (Camezind, 1974). From these, and other cytological observations, it was generally accepted that functional defects in the centromeres of E chromatids were responsible for causing elimination in cecidomyiids. So far,

nothing is known about the biochemical and molecular organization of the E-chromosomes' centromere with respect to those of S chromosomes; neither about specific DNA sequences candidates to constitute molecular chromosome landmarks for determining elimination in cecidomyiids. Both kinds of studies would no doubt shed light on the mechanisms and control of elimination.

Figure 2 shows a schematic diagram summarizing the main "lagging chromosomes" phenotypes and the emphasized elimination mechanisms.

3. Mechanisms of chromosome elimination in the male germline

In Sciaridae and Cecidomyiidae, there is an additional elimination of chromosomes in male germ cells during spermatogenesis. In this elimination event, the paternal chromosome set is discarded in Sciaridae. In Cecidomyiidae, elimination includes a haploid set of somatic chromosomes (presumably paternally derived) plus all, or nearly all, E chromosomes (reviewed in White, 1973 and Gerbi, 1986). In male meiosis I, the absence of homolog pairing, synapsis, and metaphase alignment is a common characteristic for both groups.

In sciarids, in anaphase I, only maternal (and L chromosomes when present) move toward the single pole of a monocentric first meiotic spindle, and become included into the daughter nucleus. The paternal set, in contrast, segregates away from the maternal set into a cytoplasmic bud that is later cast off from the spermatocyte (see Figure 3). Several observations support the conclusion that differential kinetic behavior of *Sciara* maternal and paternal chromosomes is accomplished by a monopolar spindle and by non-spindle cytoplasmic bud microtubules (Kubai, 1982; Fuge, 1994; Esteban *et al*., 1997). Furthermore, unorthodox microtubule-organizing centers (MTOCs) have been found to be responsible for the assembly and polarity of microtubules in the bud regions in *Sciara* spermatocytes (reviewed in Esteban *et al*., 1997). Such microtubules class are specifically involved in capturing and retaining paternal chromosomes in the spermatocytes bud. Most interesting, the presence of organized kinetochores in paternal chromosomes appears not to be necessary for their regular elimination among sciarids. Hence, an essential role of the centromeres in this kind of elimination seems to be discardable (reviewed in Goday and Esteban, 2001).

As in *Sciara*, in the cecidomyiids *Miastor*, *Heteropez,* and presumably in *Mayetiola*, a monopolar spindle directs anaphase I (Nicklas, 1959, 1960; White, 1973; Stuart and Hatchett, 1988). A haploid set of S chromosomes orientate themselves with their centromeres directed toward the single pole while the remainder (one haploid set of S chromosomes and the E chromosomes) remain, generally less condensed, in an unorientated group on the opposite nuclear side. Two kinds of secondary spermatocytes are formed that are of very different sizes, the larger being a residual cell that contains the discarded chromosomes. As in *Sciara*, the chromosomes that interact with, and migrate to, the single spindle pole are the ones that will be maintained and included in the sperm nucleus. So far, it is not known if in cecidomyiids unorthodox MTOCs generating nonspindle

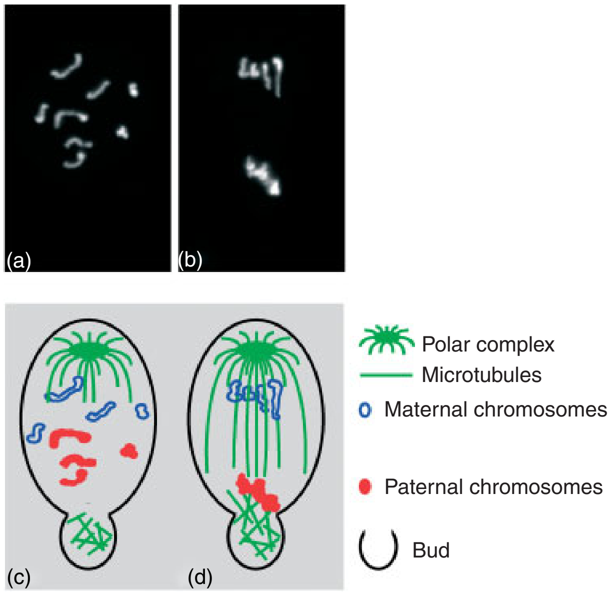

Figure 3 Chromosome elimination during first male meiosis in *S. ocellaris*. Upper row: DAPI-stained spermatocyte chromosomes. (a) Prophase I; (b) Anaphase I. Lower row: a diagrammatic representation of the same pictures illustrating the chromosome interactions with the microtubules of the first meiotic spindle and bud microtubules in the spermatocyte. (c) Prophasic chromosomes do not pair. Maternal and paternal chromosomes display a separate arrangement within the nucleus. A monopolar spindle is formed and nonspindle microtubules are generated in the cytoplasmic bud regions. (d) Maternal chromosomes move toward the single pole while paternal chromosomes segregate into the bud (Reproduced by permission of John Wiley & Sons, Inc. from C. Goday and M. R. Esteban (2001) *BioEssays*, **23**, 242–250)

microtubules are also involved, together with the spindle microtubules, in the elimination of chromosomes. If this is so, they may, as in *Sciara*, be part of the established cellular mechanism that assures the regular elimination of specific chromosomes.

A highly relevant feature, common to cecidomyiids and sciarids, is that there is a spatial compartmentalization of chromosomes within the meiotic prophase nuclei. Ultrastructural studies in the cecidomyiid *Monarthropalpus buxi* demonstrated that the non- and eliminated chromosomes are separated in the spermatogonium nucleus by a complex system of intranuclear lammellae (reviewed in Jazdowska-Zagrodzinska and Matuszewski, 1978). Similarly, in *S. coprophila* male germ cells, paternal and maternal chromosomal sets occupy distinct compartments in the meiotic prophase nuclei, and this accounts for their nonrandom chromosome segregation during anaphase I (Kubai, 1982). The territorial separation of the two chromosome sets most probably facilitates the proper interactions of each parental chromosome group with the microtubular system that further separates them at anaphase I (Kubai, 1982; Goday and Esteban, 2001). The existence of separate chromosomal territories is further supported by recent data indicating that histone acetylation between chromosomes of different parental origin highly differ, both in

	Cytological events (meiosis I)	Proposed elimination mechanisms
Sciaridae Cecydomyiidae	No pairing of homolog chromosomes No metaphase alignment Intranuclear chromosomes compartmentalization Monopolar spindle formation	Differential kinetic behavior of chromosomes at anaphase I Active role of monopolar spindle structure in capturing noneliminating chromosomes
Sciaridae	Generation of non-spindle citoplasmic microtubules	Active role of non-spindle microtubules in capturing eliminating chromosomes

Figure 4 Chromosome elimination at male first meiotic division. Summary of relevant cytological events and proposed elimination mechanisms

early germ nuclei as well as during first male meiotic division in *Sciara* (Goday and Ruiz, 2002).

The most relevant cytological events of chromosome elimination during first male meiosis and proposed mechanisms are summarized in Figure 4.

In conclusion, a common feature underlying chromosome elimination in insects is the occurrence of changes in the chromosome segregation modalities. Different tissue-specific mechanisms have evolved to achieve chromosome elimination in somatic cells and in germ cells. Modifications in centromeric functional activities and failure of sister chromatid separation are thought to account for somatic elimination events. On the other hand, chromosome elimination during gametogenesis can be conceived as the result of the combined role of a specific spindle structure (monopolar spindle) and cytoplasmic microtubules (generated by unorthodox MTOCs). The success of such a microtubule-based differential meiotic segregation seems to require a previous intranuclear specification of the chromosomal set domains.

Acknowledgments

We would like to thank Lucas Sánchez and James Haber for their valuable comments on the manuscript. We apologize to colleagues whose original research papers could not be cited because of space limitations.

Short Specialist Review

Epigenetic inheritance and RNAi at the centromere and heterochromatin

Kristin S. Caruana Scott
Duke University, Durham, NC, USA

Beth A. Sullivan
Boston University School of Medicine, Boston, MA, USA

1. Introduction

The discovery of RNA interference (RNAi) and regulatory RNAs has revolutionized views of gene regulation and chromosome structure. Originally implicated in posttranscriptional silencing, developmental regulation, and defense against transposition and viral invasion, RNAi involves the degradation of mRNA by small (21–23 nucleotide) inhibitory dsRNA duplexes (siRNAs). Argonaute, Dicer, and RNA-directed RNA polymerase (RdRP) mediate RNAi in many organisms. Dicer proteins, which are RNase III class enzymes, mediate cleavage of long dsRNAs into siRNAs. These siRNAs are incorporated into the multiprotein RNA-induced Silencing Complex (RISC) (Dykxhoorn *et al*., 2003). The antisense strand of the siRNA targets RISC to its homologous mRNA, triggering mRNA degradation or arresting the translation of mRNA into protein. Recent findings in the fission yeast *Schizosacchromyces pombe* (*S. pombe*) have uncovered a link between the RNAi pathway and assembly of pericentric heterochromatin.

2. RNAi directs heterochromatin assembly in fission yeast

Heterochromatin is a densely packaged chromatin that represses gene transcription, and is formed at repetitive DNA regions. It is required for cohesion between sister centromeres, ensuring proper chromosome segregation (Bernard *et al*., 2001; Lopez *et al*., 2000). Heterochromatin assembly depends on methylation of histone H3 at lysine 9 (H3 K9-Me) by the conserved histone methyltransferase, Clr4 [Su(var)3-9, SUVAR39H]. H3 K9-Me creates binding sites for proteins, such as Swi6 [Su(var)2-5, HP1] (Lachner *et al*., 2001), which are involved in both heterochromatin propagation and epigenetic inheritance of transcriptionally silent

chromatin (Grewal and Elgin, 2002; *see also* Article 27, **The histone code and epigenetic inheritance**, Volume 1).

Unlike higher eukaryotes, the *S. pombe* genome contains a single copy of each of the RNAi components: argonaute (*ago1*), dicer (*dcr1*), and RdRP (*rdp1*). Deleting any of these genes has no effect on cell viability. However, these mutants display chromosome segregation defects (Volpe *et al*., 2002), loss of H3 K9-Me at centromeres, and increased expression of pericentric reporter genes (Provost *et al*., 2002; Volpe *et al*., 2002). On the basis of the known RNAi pathway in nematodes and plants, RNAi machinery should process dsRNAs that originate from pericentric repeats. Indeed, ~22-nucleotide long Dicer cleavage products, complementary to both strands of centromeric repeats, called short heterochromatic RNAs (shRNAs), were detected in wild-type cells (Reinhart and Bartel, 2002).

By uncovering a novel role of RNAi components, these studies have defined a pathway for assembly of pericentric heterochromatin in fission yeast (Figure 1). First, tandemly repeated centromeric DNA is transcribed in the forward and reverse directions, producing dsRNAs. RdRP is involved in this process, perhaps to amplify RNA accumulation, since it is associated in vivo with centromeric repeats. Dicer-dependent processing of transcripts into shRNAs requires functional Ago1 and Rdp1, as well as Clr4/Su(var)3-9 (Schramke and Allshire, 2003). Once processed,

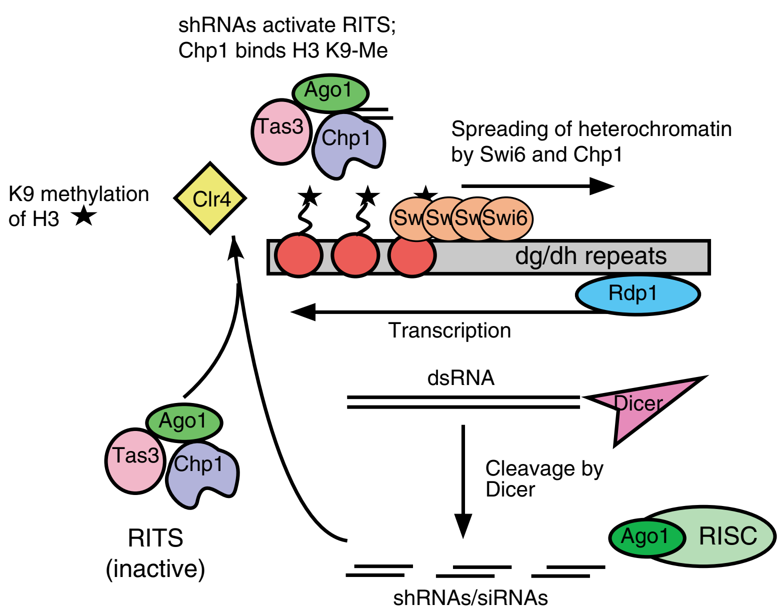

Figure 1 RNAi-dependent heterochromatin assembly at *S. pombe* centromeres. Transcripts homologous to centromeric repeats (dg/dh) (gray bar) are generated and amplified by Rdp1/RdRP and processed by Dicer into shRNAs/siRNAs. The RITS complex is activated upon interactions between Ago1 and shRNAs, and is directed to centromeric regions by the homologous small RNAs. Tas3 and Chp1 also act coordinately with the shRNAs to target the complex to nucleosomes. Clr4 methylation of H3 at lysine 9 (K9) (black stars) recruits both Chp1 and Swi6, which propagate or spread heterochromatin past the initiation site

shRNAs associate with the chromodomain protein Chp1, a component of the preassembled RITS (RNA-induced Initiation of Transcriptional Silencing) complex, which also contains Ago1 and Tas3, a novel protein that is necessary for localizing RITS to heterochromatin (Verdel *et al*., 2004). shRNA inclusion in RITS enables recognition of domains targeted for heterochromatin assembly, since, in *dcr1* mutants, the RITS complex forms, but histone modification and heterochromatin assembly is impaired. Thus, analogous to RISC, RITS directly links the RNAi components to heterochromatin through either RNA–RNA or RNA–DNA interactions (Verdel *et al*., 2004). The actions of histone deacetylases and histone methyltransferases must occur at this time, since only after lysine 9 of H3 is deacetylated can Clr4/Su(var)3-9 methylate this same residue. Swi6/HP1 and Chp1 then bind to H3 K9-Me and propagate the silent chromatin structure to surrounding sequences (see below). Remarkably, the RNAi machinery can trigger heterochromatin formation at noncentromeric sites in the presence of either a cis-linked centromere-related DNA (Hall *et al*., 2002) or by a hairpin RNA provided in trans and that has homology to a target locus (Schramke and Allshire, 2003). Moreover, Schramke and Allshire (2003) have shown that in *S. pombe*, LTRs maintain a number of meiosis-specific euchromatic genes transcriptionally silent by RNAi-dependent heterochromatin assembly.

3. How is heterochromatin maintained?

Similar to cell signaling pathways, a feedback loop may ensure heterochromatin integrity. The reverse strand of *S. pombe* centromeric repeats is always transcribed in wild-type cells, whereas the transcription of the forward strand is inhibited by heterochromatin assembly, specifically Swi6, and detected only in RNAi mutants (Volpe *et al*., 2002). Thus, stochastic loss of intact heterochromatin would catalyze the upregulation of forward-strand RNA, increasing the pool of dsRNAs available for processing and reassembly of heterochromatin over the forward-strand of centromeric repeats.

Several proteins implicated in the RNAi pathway act at multiple steps of heterochromatin assembly. For example, Chp1 associates with shRNAs in RITS, which is recruited to repetitive DNA as a complex (Verdel *et al*., 2004); it is necessary for Clr4-dependent H3 methylation at centromeres (Partridge *et al*., 2002), and finally, it binds methylated chromatin through its chromodomain (Partridge *et al*., 2000; Partridge *et al*., 2002). Thus, Chp1 may both establish and maintain pericentric heterochromatin. Clr4 is required for the processing of dsRNA transcripts by Dicer, suggesting that in addition to its downstream role in methylating histone H3, it acts coordinately, perhaps through its chromodomain, with the RNAi machinery early in heterochromatin assembly (Schramke and Allshire, 2003). Although both the chromo and SET domains of Clr4 are required in vivo for histone H3 methylation, mutations in *clr4* have varying effects on H3 K9-Me, Swi6 localization, and reporter gene silencing within pericentric heterochromatin (Nakayama *et al*., 2001). Swi6 is not required for the initial methylation event triggered by RNAi, yet it is clearly required for the spreading of H3 K9-Me beyond the sequence-specific initiation site (Hall *et al*., 2002; Schramke

and Allshire, 2003). Chp1 is also likely involved, since it binds to and directs histone H3 methylation. Although a direct interaction between Clr4 and Swi6 in *S. pombe* remains unproven, mammalian SUVAR39H has been shown to interact with HP1 to induce gene silencing, and presumably heterochromatin spreading (Schotta *et al*., 2002).

4. RNAi and heterochromatin in other eukaryotes

In Drosophila and mammals, the role of RNAi in heterochromatin assembly and function has only recently been explored. While the pathways have yet to be fully dissected, there is compelling evidence linking RNAi components to heterochromatic gene silencing in Drosophila. Single or multiple copies of a marker gene inserted within pericentric heterochromatin are subject to silencing by heterochromatin formation (Dorer and Henikoff, 1994). H3 K9-Me and heterochromatin proteins HP1 and HP2 are known to bind at the site of the silenced marker (Pal-Bhadra *et al*., 2004). Candidate genetic loci that participate in RNAi-mediated heterochromatin assembly can be identified by conserved protein motifs, such as PIWI and PAZ domains. A recent study showed that mutations in RNAi components *piwi* that encodes a PAZ domain/PIWI domain (PPD) protein, *aubergine* (*aub*), and homeless (*hls*), encoding a DEAD-motif RNA helicase, alleviated silencing of the marker gene or transgene array (Pal-Bhadra *et al*., 2004). *Piwi* and *aub* mutants partially alleviated silencing, but *hls* mutants showed dominant suppression of silencing. Accordingly, in *hls* mutants, HP1 and HP2, as well as H3 K9-Me, were markedly decreased within the pericentromeric regions and at the site of the normally silent marker genes. Even more striking, though, was the observation that these proteins were dramatically redistributed from the typically heterochromatic chromocenter to euchromatin. Similar effects on nuclear and chromosome architecture have been observed for the localization of Swi6 in RNAi mutants in *S. pombe* (Hall *et al*., 2003). Thus, RNAi has an additional, profound role in chromatin organization within distinct nuclear and chromosomal compartments.

Vertebrate centromeres are also located in repetitive DNA (Sullivan *et al*., 2001), and it is reasonable to assume a link between transcripts from centromeric repeats and the RNAi pathway. Studies in mouse suggest that RNA may be involved in pericentric heterochromatin assembly, as H3 K9-Me cannot be detected at centromeres after ribonuclease treatment of permeabilized mouse cells (Maison *et al*., 2002). Although transcripts homologous to centromeric satellite sequences in mice have been reported, a direct relationship between RNA–RNA or RNA–DNA interactions and heterochromatin assembly has not been demonstrated (Lehnertz *et al*., 2003; Rudert *et al*., 1995).

Centromeric DNAs, including satellite repeats and transposons, have historically been considered “junk DNA”, and it has been assumed that centric heterochromatin serves as a dumping ground for these elements and their relics. However, the demonstration that LTRs can regulate gene expression through the RNAi pathway (Schramke and Allshire, 2003) raises the possibility that these elements are actively involved in establishing pericentric heterochromatin. In addition to satellite DNAs, transposon- and LTR- like sequences are often found within or near centromeres

of higher eukaryotes. Intriguingly, de novo centromere function, as assayed by the presence of kinetochore proteins, cannot occur in the absence of a CENP-B box, a transposon-like motif present within human alpha satellite DNA (Ohzeki *et al*., 2002). Furthermore, some neocentromeres (centromeres formed on noncentromeric DNA) are flanked by or are within regions that are enriched for LTRs and/or tandem repeats. One intriguing possibility is that LTRs and the RNAi pathway create a heterochromatic environment flanking that promotes and regulates centromeric chromatin assembly.

Much remains to be learned about RNAi and epigenetic centromere assembly and regulation, but the importance of RNA–RNA or RNA–DNA interactions in chromosome structure and the complex inheritance of genome modification is an emerging theme. Future studies are needed to dissect the steps involved in targeting of RNAi machinery to specific sequences. Many of the genes required for RNAi are redundant in higher eukaryotes, indicating added levels of complexity in chromatin organization and regulation. A better understanding of the link between the RNAi pathway and heterochromatin assembly will also advance our knowledge of the formation of specialized nuclear and chromosomal domains, and the overall impact of these domains on chromosome biology and gene expression.

Basic Techniques and Approaches

Techniques in genomic imprinting research

Todd A. Gray
Wadsworth Center, The Genomics Institute, Troy, NY, USA

1. RT-PCR of transcribed polymorphisms

Demonstration of parentally determined monoallelic transcription represents the gold standard in imprinted gene evaluation. One prerequisite for this analysis is that individuals being tested have a sequence difference, or polymorphism, in the candidate gene that can be used to distinguish the maternally and paternally derived alleles. For example, a "G" may be found in a specific position in a candidate gene from the mother, and a "T" in this same position in the gene from the father (Figure 1a). If the polymorphism is located in an exon of the gene, then the parental origin of the mRNA transcripts can be distinguished (Figure 1b). mRNAs prepared from such an informative individual are reverse transcribed (RT) into matching complementary DNA (cDNA), and are amplified by the polymerase chain reaction (PCR) to allow analysis of this gene's mRNAs out of the thousands of others in the original sample. Amplified cDNA products from the pool of mRNA transcripts subjected to this RT-PCR approach are inspected, usually by direct sequencing or by sequencing of >10 individual clones, to determine whether both, or only one, of the polymorphisms is present in the sample (Bonthron *et al*., 2000; Yin *et al*., 2004). Recovery of approximately equivalent levels of each polymorphism indicates biallelic expression, while the finding of only one of the two genomic polymorphisms in the cDNA pool suggests monoallelic expression consistent with imprinting (Figure 1b).

Since monoallelic expression can result from other epigenetic phenomena (e.g., X-inactivation (Lyon, 1999), mutual exclusion (Serizawa *et al*., 2000), aberrant gene silencing (Esteller, 2002)) or genetic alterations (e.g., promoter mutations, mRNA destabilizing changes such as certain premature protein truncation mutations (Frischmeyer and Dietz, 1999)), independent verification is necessary. For humans, verification usually means examination of additional parent/child subjects for other informative polymorphisms, or analysis of reciprocal transmission of the silenced allele from a parent of the other sex. In lab animals, such as mice, verification is systematically accomplished by reciprocal breeding in which the maternal strain in one mating is used as the paternal strain in another mating; if the monoallelic expression is due to imprinting, the gene from that strain should be actively transcribed in the pups from one cross, but silenced in the other.

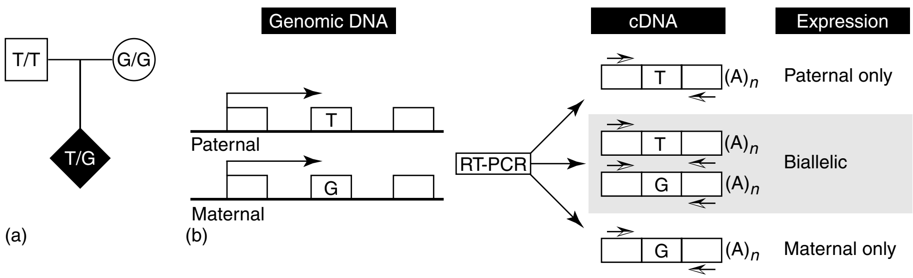

Figure 1 Assessment of monoallelic transcription by PCR amplification of expressed polymorphisms. (a) A simplified pedigree showing a homozygous T/T father, G/G mother, and heterozygous T/G offspring for a hypothetical candidate gene. (b) RT-PCR amplification of the candidate gene's mRNA products. Each parental genomic DNA structure is shown as three exons, with the embedded T or G polymorphism. Following reverse transcription of the mRNA, the cDNA is PCR-amplified and analyzed for the presence of the T or G polymorphism

Often, RNA samples are not available, thus precluding the relatively definitive RT-PCR analysis. DNA samples, in contrast, are much more widely available. Fortunately, DNA methylation of cytosine at cytosine/guanosine nucleotide tandems (CpG dinucleotides) near the start of a gene correlates with expression, such that actively transcribed genes are associated with unmethylated CpGs, whereas methylated CpG dinucleotides are associated with transcriptionally silent genes. Traditional methods of examining CpG methylation utilized restriction enzymes that could only cut DNA whose cognate sites had unmethylated CpGs (Kubota *et al*., 1996). This method is reproducible and unambiguous, but it requires a comparatively large amount of DNA, suitable restriction sites in the region of interest, and radioactive probes, and it has limited throughput. Current methods use the power of PCR amplification for similar analyses that bypass some of these drawbacks.

PCR amplification alone, however, cannot discriminate methylated from unmethylated template DNA. The epigenetic information contained in the cytosine methylation pattern of genomic DNA must first be converted into genetic, or sequence, information. To this end, bisulfite-conversion methodologies have been refined and implemented (Clark *et al*., 1994; Frommer *et al*., 1992; Herman *et al*., 1996; Sadri and Hornsby, 1996). The basic procedure is predicated on the conversion of cytosine, but not methyl-cytosine, to uracil upon exposure to high concentrations of sodium bisulfite, under certain conditions. All non-CpG cytosines will be converted to uracil, as will unmethylated CpG cytosines, but methylated CpG cytosines will remain unchanged (Figure 2). DNA that has been bisulfite-converted is used as a template for PCR amplification, with the newly created uracils recognized as thymidines.

The bisulfite-conversion process has harsh effects on the DNA (Grunau *et al*., 2001), and the loss of nearly all of the cytosines in the template DNA impairs the robustness and specificity of PCR amplification (Warnecke *et al*., 2002). Two rounds of amplification are therefore common, in which amplification is initially performed with primers that do not contain CpGs, and therefore do not discriminate between methylated and unmethylated samples. This round is intended to amplify the target sequence as template for a second round of amplification with primers

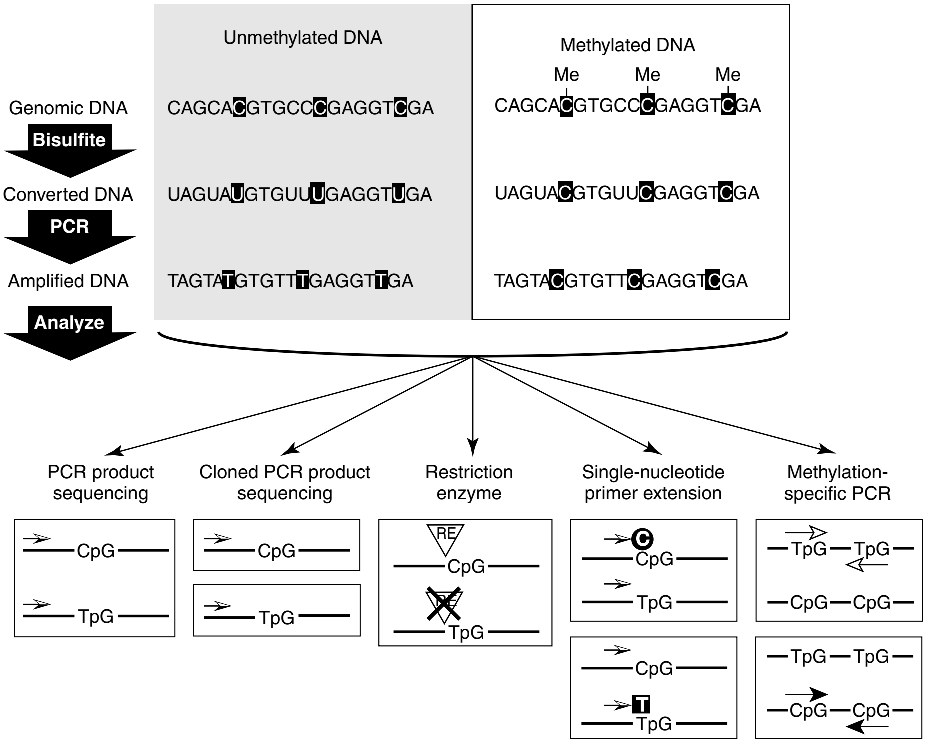

Figure 2 Bisulfite conversion and PCR evaluation of cytosine methylation in genomic DNA. Subjecting genomic DNA to a bisulfite-modification procedure converts cytosines to uracils, while methyl-cytosines are protected from conversion. Two successive rounds of amplification (nested PCR) are typically performed, to enhance sensitivity. Comparison of the amplified products for converted thymidines and protected cytosines reveals the methylation profile of the original template. Simplified schematic diagrams illustrating the basis of each assay are shown below, with each rectangular box representing individual reactions

that lie within the amplified interval. The resulting products can be analyzed for the presence of a thymidine or cytosine at CpGs in the candidate gene interval using many common genetic analysis tools (Figure 2). As with the first primer set, the second primer set may be nondiscriminatory, so that it will amplify all target fragments, regardless of original methylation status. These products are analyzed through: (1) sequencing of the PCR products either directly or as a subset of cloned PCR products (Frommer *et al*., 1992), (2) restriction enzyme analysis that will only cut converted DNA in which a specific cytosine has been either retained or transformed, but not both (Sadri and Hornsby, 1996; Xiong and Laird, 1997), and (3) single-nucleotide primer extension (SNuPE), in which an internal primer hybridizes adjacent to a specific CpG dinucleotide, and is incubated with a polymerase extension mix that contains only either labeled thymidine or cytosine dideoxynucleotides to generate single base extension products only from unmethylated or methylated templates, respectively (Gonzalgo and Jones, 1997). As an alternative, two sets of second-round primers may be used that discriminate between cytosine- and thymidine-containing templates. In this methylation-specific

PCR (Herman *et al*., 1996), an "unmethylated" primer set contains thymidines where all cytosines had originally been, and a "methylated" primer set contains cytosines at CpG dinucleotides. No one method is inherently the best, and which one is used will depend on technical resources and expertise, as well as features of the individual gene being assayed. Higher-throughput approaches are also being devised that facilitate the simultaneous analysis of many samples (Akey *et al*., 2002; Cottrell *et al*., 2004; Eads *et al*., 2000; Rand *et al*., 2002).

While the methods outlined above address the methylation status at specified genomic loci, screening procedures have been developed that first identify a difference in methylation, followed by locus identification. These procedures are remarkably diverse and employ methyl-sensitive restriction enzymes, bisulfite treatment, electrophoresis, or microarray platforms (Laird, 2003).

Definition of the profile of cytosines and thymidines in bisulfite-converted DNA allows the epigenetic methylation profile of the target sequence in the original sample to be inferred. Regardless of the assay used, a hallmark of imprinted genes is that they predictably exhibit a 50% (differential) methylation profile, with the copy from one parent being transcribed and generally unmethylated, and the copy from the other parent being transcriptionally silent and hypermethylated. In addition to their use in detection of imprinting, bisulfite-conversion methodologies are applicable to epigenetic analyses of cancer, aging, and mammalian cloning. As epigenetic profiling continues to gain prominence, new, higher-throughput, and more cost-effective technologies are likely to be developed, facilitating their routine application in both research and clinical settings.

Bioinformatics and the identification of imprinted genes in mammals

Melissa J. Fazzari and John M. Greally
Albert Einstein College of Medicine, Bronx, NY, USA

Currently, we know of the existence of tens of imprinted genes in human and mouse (Greally, 2002), representing only a fraction of the hundreds of imprinted genes that are predicted (Reik and Walter, 2001). It is technically difficult to prove that a gene is imprinted (Suda *et al*., 2003), as the assay has to be able to quantify the relative amount of expression from the paternal and maternal alleles of the gene, and may require isolating a specific cell type (Yamasaki *et al*., 2003) or developmental stage (Moore *et al*., 2001) for analysis (*see* Article 44, **Techniques in genomic imprinting research**, Volume 1 and Article 46, **UPD in human and mouse and role in identification of imprinted loci**, Volume 1). In the meantime, population geneticists have begun to recognize the increasing numbers of genetic diseases with parent-of-origin effects on their inheritance (Green *et al*., 2002; Karason *et al*., 2003; McInnis *et al*., 2003; Pezzolesi *et al*., 2004; Strauch *et al*., 2001; *see also* Article 26, **Imprinting and epigenetic inheritance in human disease**, Volume 1). When faced with a region of peak linkage, often millions of base pairs in size and containing dozens of genes, candidates for targeted analysis might currently be chosen on the basis of their functional properties. If parent-of-origin effects were noted, a further useful indicator of the gene responsible for the disease would be a characteristic predictive of its likelihood of imprinting.

Whole-genome approaches to predict imprinted gene status have been performed in two ways. Direct molecular analysis has been performed to try to identify loci at which gene expression (Nikaido *et al*., 2003) or cytosine methylation (Shibata *et al*., 1994) patterns differ on the paternal and maternal chromosomes. The focus of this review is the alternative, bioinformatic approach, based on our appreciation that imprinted genes have discriminatory sequence characteristics (Greally, 2002; Ke *et al*., 2002a; Ke *et al*., 2002b). However, as we stress again later, these are complementary, not competing approaches – concordance of predictions by multiple independent approaches would be expected to be more powerful than individual predictions alone.

The bioinformatic prediction of imprinted genes is predicated on the presence of sequence features at imprinted loci that discriminate them from nonimprinted loci. Our study of the 100-kb context of imprinted promoters revealed an unexpected

dearth of short interspersed nuclear elements (SINEs) (Greally, 2002). Nonimprinted loci can accumulate SINEs to similar low levels, so a comparison based on this sequence feature alone is very nonspecific. Other sequence features, in conjunction with our knowledge of SINE content, may further distinguish imprinted genes. Therefore, it becomes necessary to study imprinting in a multivariable setting, using statistical models that can accommodate more than one feature. By identifying discriminatory sequence features, these models provide insight (both mechanistic and evolutionary) into the underlying biology of the system, as well as a means to help predict whether imprinting is occurring at the remaining genes in the genome.

Statistical modeling allows each gene of unknown status to be assigned a predictive score, or relative likelihood of imprinting. We attempt to summarize sequence content information simultaneously through a multivariable model, which uses these characteristics as inputs and weights them on the basis of their relative effects on the probability of imprinting. Logistic regression modeling, a well-studied and powerful approach for binary outcome data (Hosmer and Lemeshow, 1989), models the log odds of imprinting probability using a linear combination of the predictors. Other methods may be used to generate predictive models (Bishop, 1995; Breiman *et al*., 1984; Fisher, 1936), but performance has been shown to vary with respect to different datasets examined, with no method consistently outperforming the others.

The statistical challenges in the prediction of imprinting are numerous. The small number of known imprinted genes (Greally, 2002) limits the size and complexity of the model that can be estimated. Adding features will always allow a better fit of the model to the data in hand, but this perfect fit will almost certainly mean poor predictions when applied to new samples of genes. This poor generalization is due to the model's fitting of each nuance in the data, rather than capturing only those effects that will be consistent from sample to sample. At the other extreme, low-complexity models that underfit the data may be quite biased. In this application, the number of candidate predictors that can be mined from sequence data annotations (such as those at the UCSC Genome Browser **http://genome.ucsc.edu/**) is in the hundreds, with varying levels of correlation. It is likely that the majority of these features have small to negligible effects. Model selection techniques must therefore be employed to find models that capture the bulk of the information available, without overfitting. Validation of the model is difficult since additional test samples are nonexistent; we must rely on computer-intensive methods (Hjorth, 1994) to gain a sense of predictive ability.

We show the principle of this approach in the following analysis. We used a logistic regression model to predict imprinting, mining DNA sequence annotations (repetitive element cumulative number and size, CpG island number) for the 10- and 100-kb regions flanking the transcription start sites for 28 human imprinted genes and 300 randomly chosen control loci. Model selection was performed using the "all subsets" approach and the Akaike's Information Criterion (AIC) (Akaike, 1973) as a measure of model information. This criterion is a useful measure of the model's predictive ability, while providing a penalty for model complexity. The model that we derived is representative of many competing imprinting models and is a function of five sequence characteristics:

Alu SINEs	(100 kb)
CR1 LINEs	(100 kb)
CR1 LINEs	(10 kb)
Low-complexity repeats	(10 kb)
Tip100 DNA elements	(100 kb)

The previous report of SINE exclusion from the 100-kb flanking promoters of imprinted genes (Greally, 2002) is confirmed with this analysis, while additional sequence features are also found to discriminate imprinted loci (the ancient chicken repeat 1 (CR1) LINEs, low-complexity repeats, and the Tip100 DNA transposon). To evaluate this model, general measures of predictive power may be obtained (Agresti, 1990). In the reported model, the area under the Receiver Operating Curve (ROC) is 0.91. The generalized R-square statistic (based on the log-likelihood) is 0.42. On the basis of these measures, we can reasonably conclude that sequence characteristics contain information with respect to imprinting status and that the model may be used as an analytic tool to highlight genes with the highest evidence of imprinting.

Predictive scores derived from the logistic model may be used to rank genes on the basis of imprinting evidence (Figure 1). This analytic approach is common in many areas of research, and has been successfully applied in clinical trials to

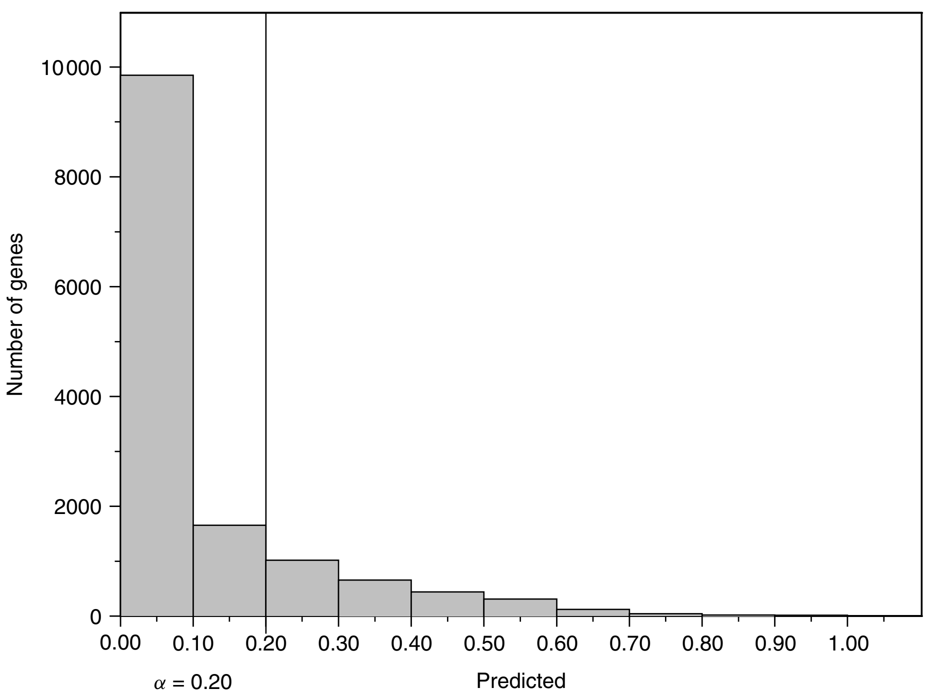

Figure 1 Genome-wide distribution of predicted scores based on logit model. Genes with scores below a threshold level (α) have the lowest probability of imprinting based on sequence features. Sensitivity and specificity of predictions are direct functions of the threshold specified

stratify patients on the basis of risk (Gail and Costantino, 2001). Consideration of the highest-ranked genes may offer information that, in conjunction with other discovery methods, quickly and systematically finds new imprinted genes.

On the basis of the sequence characteristics of the regions flanking gene promoters, we can assign a relative likelihood of imprinting to every gene in the genome. There are several ways by which we can improve our predictive capabilities, however. It is striking that certain promoters exist embedded within imprinted domains that escape imprinting (Hayward *et al*., 1998; Vu and Hoffman, 1994), indicating that flanking sequences are not the sole genomic determinant of imprinting. Identification of the sequences that discriminate imprinted from nonimprinted promoters may add a lot of power to bioinformatically based predictions of imprinted genes. As the human and mouse genomes become better annotated, especially with regard to promoter sites, that will allow much better sample assembly. The integration of bioinformatic with molecular predictions should also allow us to explore how much concordance exists between these datasets. In addition, novel statistical methods in model selection can be explored to further identify and characterize informative sequence features. As a final point, predictions are just predictions – how well they perform will be apparent only with testing, which is beyond the scope of any single laboratory, so these predictions need to be made publicly available for testing by investigators interested in different regions of the genome.

UPD in human and mouse and role in identification of imprinted loci

Aaron P. Theisen
Health Research and Education Center, Washington State University, Spokane, WA, USA

Lisa G. Shaffer
Sacred Heart Medical Center, Washington State University, Spokane, WA, USA

Although most mammalian autosomal genes are biallelically expressed, a small number are functionally haploid with one of the parental contributions silenced while the homologous allele is active. "Genomic imprinting" refers to an epigenetic mark of the DNA, or associated proteins, that stably switch genes "on" or "off" depending on their parent of origin. Thus, genomic imprinting refers to a normal state of genomic imbalance. The search for imprinted genes began with the serendipitous detection of genomic alterations that unmasked candidate loci through their overexpression or lack of expression.

The pioneering nuclear transfer technique developed by Surani *et al*. (1984) confirmed that mammalian development required the contribution of both the maternal and paternal genomes. Exploiting the separation of the maternal and paternal nuclei shortly after fertilization, researchers removed the sperm-derived pronucleus and replaced it with a second egg-derived pronucleus. The gynogenetic embryos failed to develop normally, as did the alternative experiment with androgenetic embryos. The authors concluded that genomic imprinting occurred during gametogenesis such that the absence of contribution of active genes from one of the parental genomes resulted in the failure of proper embryonic development.

The first suggestion that specific chromosomal regions contained imprinted genes necessary for proper development came from earlier work with uniparental disomic (*see* Article 19, **Uniparental disomy**, Volume 1) mice, which received two copies of a chromosome or chromosomal region from one parent with no contribution from the other parent. The process of generating mice with whole-chromosome or partial uniparental disomies (UPDs), termed "translocation intercrossing", was developed by Snell in 1946. Because gametes carrying a translocation are susceptible to nondisjunction (*see* Article 16, **Nondisjunction**, Volume 1), if two mice carrying the same translocation are intercrossed, a subset of offspring should receive

two complementary aneuploid (either missing or carrying an extra chromosome involved in the translocation) gametes, forming a viable, chromosomally balanced zygote. If one of the mice involved in the intercross carries homozygous alleles for a suitable marker gene, the parental origin of the whole-chromosome or partial UPD can be identified (Snell, 1946).

Intercrosses of mice carrying reciprocal translocations (the exchange of chromosomal segments between nonhomologous chromosomes) are complicated by the types of chromosome segregation required to produce UPDs either proximal or distal to the translocation breakpoint. Balanced zygotes with duplications of regions distal to the translocation breakpoint require the relatively common adjacent-1 segregation of gametes; up to 16% of zygotes will mature into viable offspring. However, offspring with duplications proximal (centromeric) to the translocation breakpoint require the much rarer adjacent-2 segregation of gametes; recovery rates of these types of offspring are much lower than for distal-duplication mice, with 5% or less of zygotes resulting in live offspring (Searle *et al*., 1971). Based on the methods of calculating nondisjunction rates for mice with reciprocal translocations, Lyon *et al*. (1976) estimated the recovery rate for the offspring of mice with Robertsonian translocations (the centric translocations of the long arms of two chromosomes) to be 0–5%; the majority of zygotes will be unbalanced (monosomic or trisomic) and usually die preterm.

By comparing the percentage of viable offspring with that expected of adjacent-1 or -2 segregation, mouse reciprocal translocations could be used to identify the location of the centromere of one of the chromosomes involved relative to the translocation breakpoint (Searle *et al*., 1971). However, in some studies, the homozygous-marker offspring failed to appear in the litter or died shortly after birth. The first evidence that “complementation errors” might arise as a result of uniparental disomy for a chromosome region occurred in studies of the hairpin-tail T^{hp} allele on mouse chromosome 17, whereby inheritance of the allele from the mother resulted in death at birth or in utero, whereas paternal inheritance of the allele produced viable offspring (Johnson, 1974). Further studies by Searle and Beechey (1978) demonstrated the noncomplementation and resultant abnormal phenotypes of maternal duplications (and complementary paternal deficiencies) of distal mouse chromosomes 2, 7, and 8.

Following the successes of the early nuclear transfer experiments, researchers, using mice carrying translocations, discovered that maternal and paternal contributions of some mouse chromosomal regions could produce opposite growth effects: mice with Robertsonian translocations involving chromosomes 11 and 13 revealed that maternal UPDs of chromosome 11 resulted in offspring smaller than their littermates, whereas paternal UPDs of chromosome 11 produced mice significantly larger than their littermates. Reciprocal translocations involving chromosomes 2 and 11 confirmed that the growth effects were of proximal chromosome 11 origin (Cattanach and Kirk, 1985).

Although nuclear transfer experiments have confirmed that the parental genomes make differential contributions to development and narrowed the “imprinting window” in which these epigenetic marks are established, the search for imprinted loci has relied on imprinting map positions derived from studies of mouse whole-chromosome and partial UPDs. The imprinting maps, previously updated

annually and now available on-line (**http://www.mgu.har.mrc.ac.uk/research/imprinting**, 2005) indicate those areas of the mouse genome that have demonstrated differential growth or developmental defects in mice with UPDs.

Imprinted chromosomal regions may compose 10–25% of the mouse genome (Cattanach and Beechey, 1997), although estimates of the number of individual imprinted genes suggest that these constitute a lower percentage of all genes. Although a similar estimate has not been made for humans, the high homology between the mouse and human genomes has allowed researchers to identify those genes that are imprinted in the mouse genome that should display phenotypic effects in humans (**http://www.mgu.har.mrc.ac.uk**). Confirmation of the phenotypic effects, if any, of these imprinted loci depends on the discovery of rare individuals with UPDs of the corresponding chromosome.

Two individuals with maternal disomy for chromosome 15 and Prader–Willi syndrome (PWS) (*see* Article 29, **Imprinting in Prader–Willi and Angelman syndromes**, Volume 1), a disorder characterized by obesity and mental retardation, provided the first demonstration that UPD could be associated with human diseases arising from the imbalance of imprinted loci (Nicholls *et al*., 1989). Comparisons of the phenotypes of UPDs with those regions of the human and mouse genomes thought to contain imprinted loci have identified regions of genomic imprinting for chromosomes 6, 7, 11, 14, and 15 and phenotypes suggestive of imprinting effects on chromosomes 2, 9, 16, and 20 (Ledbetter and Engel, 1995; Kotzot, 1999). Although the same experiments that generate UPDs in mice cannot be performed in humans, the relatively high incidence of Robertsonian translocations in the general population (∼1:1000), coupled with the high proportion of structural chromosomal abnormalities resulting in UPD that are Robertsonian translocations (Shaffer, 2003), illustrates the importance of identifying imprinted loci in humans.

The search for imprinted loci using UPDs in mice and humans relies on several assumptions. First, although most imprinted genes are conserved between humans and mice, expression profiles have identified several that are not. For example, *U2afbp-rs* is imprinted in mice but not in humans, and conflicting reports suggest that *Igf2r*, which is imprinted in mice, may be biallelically expressed in humans (Kalscheuer *et al*., 1993). Furthermore, researchers have only been able to identify those regions in mice with easily recognizable phenotypes. Lethal imprinting effects that may be construed as nonheritable disease alleles due to a lack of observed offspring provide a confounding corollary for investigations into human imprinted loci.

Nonetheless, the search for imprinted loci in mice and humans using UPDs may continue to reveal imprinting regions in both species. Several chromosomes that display parent-of-origin effects have yet to have genes mapped to those regions (**http://www.mgu.har.mrc.ac.uk**), and UPDs for a few mouse chromosomes have not been generated or thoroughly investigated owing to a lack of suitable translocations or marker genes. Likewise, confirmation of regions of homologous imprinting loci in humans awaits the ascertainment of UPDs for those chromosomes, including chromosomes 18 and 19 (Shaffer, 2003). Just as the identification of disease-causing genes often awaits the ascertainment of the rare chromosomal rearrangement that disrupts their function (*see* Article 11, **Human**

cytogenetics and human chromosome abnormalities, Volume 1), the search for imprinted loci and the deleterious effects of their misexpression relies upon the discovery of the rare case of UPD that unmasks their existence.

Introductory Review

Introduction to gene mapping: linkage at a crossroads

Nancy J. Cox
The University of Chicago, Chicago, IL, USA

1. Introduction

The success of gene mapping in Mendelian disorders has been remarkable; the general paradigm of linkage mapping followed by positional cloning has become near-foolproof for identifying the genetic variation responsible for disorders with a simple relationship between genotype and phenotype. Both the linkage mapping and the positional cloning studies of simple, Mendelian disorders have been accomplished with increasing speed and efficiency as human genomic resources have been developed and become more affordable. But the paradigm used so successfully for Mendelian disorders is widely perceived as being notably less successful in applications to complex disorders. Complex disorders are those that have a significantly elevated risk in relatives of an affected individual as compared with disease risk for the general population, but for which simple genetic models of transmission can be excluded. Such disorders, including asthma, cardiovascular disease, diabetes, familial cancers, and psychiatric disorders, are relatively common compared with disorders having simple, Mendelian patterns of transmission, and collectively contribute substantially to public health care expenditures. Complex disorders are generally believed to arise as a consequence of the actions and interactions of many risk factors, both genetic and nongenetic. Successful identification of genetic risk factors for these disorders should improve both our understanding of the primary pathophysiology of the disorders, and ultimately our ability to treat and/or prevent them. In particular, identification of genetic risk factors may allow us to improve the design of large-scale epidemiological studies, allowing the discovery of more specific nongenetic risk factors that might be cost-effective targets for disease prevention strategies.

We, as a society, have made substantial investments in genetic science and genomic technologies, and the expectations for returns on those investments are understandably high. Given these expectations, and our experience to date in applying genetic and genomic technologies to identify and characterize the genetic component to complex phenotypes, what is the right road forward? Can we modify the gene-mapping paradigm developed for Mendelian disorders to yield better success for complex phenotypes than we have enjoyed to date? Or is gene

mapping the wrong paradigm for understanding the genetic component to complex phenotypes? In the following sections, we will consider the recent methodological improvements to gene mapping, key questions related to the measurement of complex phenotypes, and novel approaches to gene mapping. The intent is not to provide a set of directions, sending readers to one road or another, but rather to illuminate the roadway.

2. Better methods for better results?

Among the first of the challenges for mapping complex phenotypes was the recognition that genetic models for these phenotypes were unknown, a considerable contrast to the largely transparent models used for Mendelian disorders. The evolution of approaches for linkage mapping that do not require specifying genetic models and the subsequent controversies on the merits of model-free approaches to gene mapping relative to the more traditional approaches requiring knowledge and specification of genetic models are summarized in Article 48, **Parametric versus nonparametric and two-point versus multipoint: controversies in gene mapping**, Volume 1. The recognition of the value of the additional information obtained through the use of multiple markers simultaneously led to the development of algorithms for multipoint linkage mapping (Lathrop *et al*., 1984; Lathrop *et al*., 1985). The simultaneous stimulation provided by the development of multipoint algorithms for linkage mapping, and the development of different approaches (parametric and model-free) for assessing the evidence for linkage led to a series of advances in the computational algorithms for linkage mapping, summarized in Article 52, **Algorithmic improvements in gene mapping**, Volume 1. The most commonly used algorithms in linkage mapping involve a trade-off between the number of markers that can be simultaneously considered and the number of individuals in the pedigree that can be used in analysis. Thus, the conventional wisdom on the optimal size and structure of families for gene mapping has often been confounded by the most recent advances in algorithmic development (Cox, 2001), and the optimal choice of population as well as family size and structure remains a subject of considerable discussion (*see* Article 51, **Choices in gene mapping: populations and family structures**, Volume 1).

The initial difficulties in successfully mapping genes for complex disorders led to the development of approaches allowing for considerably more sophisticated genetic complexities, such as imprinting and epigenetic phenomena (*see* Article 49, **Gene mapping, imprinting, and epigenetics**, Volume 1). Similarly, it was realized that multipoint mapping was far from perfectly informative, and that measures of information content (*see* Article 53, **Information content in gene mapping**, Volume 1) might provide additional insight into how linkage-mapping results could be improved. Sex-averaged maps have generally been used in linkage mapping studies, despite the knowledge that male and female genetic maps differ considerably. Recent mapping approaches (*see* Article 54, **Sex-specific maps and consequences for linkage mapping**, Volume 1) try to make better use of information on the differences in male and female genetic maps. While genotyping accuracy has almost certainly improved since the initial use of DNA

genotypes in linkage mapping, there are a variety of approaches for identifying and accommodating genotyping errors that should improve the quality of inferences from linkage analysis. We also have a growing appreciation of the variability of the human genome outside the site polymorphisms and simple length polymorphisms that we have commonly used as genetic markers. Polymorphic inversions, duplications, and deletions affect linkage mapping and make up at least part of the genetic component to a variety of complex disorders (*see* Article 55, **Polymorphic inversions, deletions, and duplications in gene mapping**, Volume 1). Our ability to detect and characterize these cytogenetic polymorphisms will increase as we utilize denser single-nucleotide polymorphism (SNP) maps in linkage studies, although there are real trade-offs in moving from the more highly polymorphic single tandem repeat polymorphisms (STRPs) to biallelic SNPs (*see* Article 50, **Gene mapping and the transition from STRPs to SNPs**, Volume 1).

Have all of these improvements in the methods we use to conduct linkage-mapping studies increased our ability to localize genes for complex phenotypes? It is hard to believe that we could have had much success in mapping complex disorders using two-point parametric analysis with the sparse genetic maps of the 1980s. But, as noted in the Introduction, we are not reliably successful at linkage mapping of complex disorders even with all of the advances in analysis methods and genotyping technologies that we currently enjoy.

3. The alternative route

Genome-wide association mapping has been suggested as an alternative to linkage mapping, particularly for complex disorders in which individual genetic risk factors may be sufficiently modest to preclude detection in linkage studies (Risch and Merikangas, 1996). The technology is now available to tackle these studies (Altshuler and Clark, 2005), and early successes (e.g., Klein *et al*., 2005) will likely lead to increased use of this approach. Linkage mapping, nevertheless, retains substantial appeal. We expect the magnitude of the signals for linkage mapping to reflect the magnitude of the contribution the locus makes to the genetic component to disease. That will not be the case for genetic risk factors identified through association mapping. However challenging and difficult the linkage mapping and positional cloning studies are, they are but a prelude to the functional and physiological studies that inevitably follow. It seems easier to justify those follow-up studies when they will be conducted on the genetic risk factors making the largest contributions to disease.

Moreover, there are reasons to be optimistic about the prospects for greater success in linkage mapping as we consider more informative phenotypes. A key challenge for all genetic studies on disease phenotypes is that the diagnostic criteria reflect clinical, rather than genetic, utility. There is increased emphasis on phenotypic characterization, and it is quite possible that increased phenotypic homogeneity will frequently be associated with increased genetic homogeneity, and attendant increases in power for linkage mapping. Similarly, with careful attention to study design, the gene mapping of quantitative phenotypes, including those related to disease, seems within reach (see Blangero, 2004, for a recent review).

Finally, there is a growing recognition that disorders with substantial nongenetic risk, as exemplified by rapid changes in prevalence (e.g., diabetes, asthma, obesity), may be more amenable to mapping by focusing on aspects of the phenotype that are relevant to the ultimate gene-by-environment interaction – natural selection (*see* Article 7, **Genetic signatures of natural selection**, Volume 1). For example, polymorphisms associated with salt-sensitive hypertension have allele frequencies showing a significant correlation with latitude (Thompson *et al*., 2004), consistent with the hypothesis that spatial variability in selection pressures have shaped the allele frequencies at these loci. This suggests an alternative approach for gene mapping that focuses on the correlation of allele frequencies in native human populations with measures of environment, such as latitude, that may reflect the effects of variation in natural selection.

There will, no doubt, be further advances in genomic technology and in computational biology that will enhance our ability to identify genetic variation for complex phenotypes. With equal certainty, geneticists will continue to debate the best road to take to future gene mapping studies. At the very least, we can expect an interesting ride.

Introductory Review

Parametric versus nonparametric and two-point versus multipoint: controversies in gene mapping

Joan E. Bailey-Wilson
National Human Genome Research Institute, Baltimore, MD, USA

1. Introduction

In parametric or model-based linkage analysis (often called LOD score linkage analysis (*see* Article 47, **Introduction to gene mapping: linkage at a crossroads**, Volume 1 and Article 56, **Computation of LOD scores**, Volume 1)), one assumes that models describing both the trait and marker loci are known without error. This means that one assumes that the allele frequencies, dominance relationships among the alleles, and relationships between genotypes and phenotypes are known without error at both the trait and marker loci. Nonparametric (or model-free or weakly parametric) linkage methods make fewer assumptions about the trait model, although the assumption that the marker locus model(s) is known without error is still in force. These methods of analysis have different strengths and weaknesses that should be taken into account by the analyst when choosing how to analyze linkage data. Both parametric and nonparametric analyses may be performed between a trait locus and a single marker locus (two-point linkage) or between a trait locus and a map of multiple markers (multipoint linkage). Again, these methods have different strengths and weaknesses that should be understood before embarking upon their use.

2. Parametric versus nonparametric linkage

It is well known that when both the trait and marker locus models are specified without error, then parametric linkage analysis is more powerful than nonparametric linkage and there is no inflation of Type 1 error rates asymptotically (Amos and Williamson, 1993). However, if either the trait or marker locus models are misspecified in the analysis, then the power of parametric linkage is decreased and, in some situations, may be exceeded by the power of some nonparametric methods (Amos, 1988; Williamson and Amos, 1990). Furthermore, when both the trait and the marker locus models are misspecified, the Type 1 error rate of parametric linkage analysis is increased over the nominal level (Williamson and Amos, 1990).

In situations in which no marker data are available on parents, correct specification of the trait model but incorrect specification of the marker locus model can also lead to inflated Type 1 error rates (Mandal *et al*., 1998). The effect of misspecification of marker locus models on nonparametric linkage methods has been shown to vary depending on the type of test. Tests that rely on identity-by-state methods have been shown to have inflated Type 1 error rates if marker models are misspecified (Weeks and Lange, 1988) but at least some methods that use identity-by-descent methods (such as the Haseman–Elston sib-pair regression test) have been shown to be quite robust (Mandal *et al*., 1999, 2001). All further discussion in this section will assume that the marker locus model is correctly specified in the analyses.

Many authors have shown that various nonparametric methods may be weakly parametric in that they may have maximal power under certain genetic models or that they reduce the genetic model to simpler models with fewer parameters such as regression coefficients or variance components. It has been shown for affected sib-pair (ASP) data that the mean test is equivalent to a test based on a simple recessive model LOD score, and equivalences have also been shown between particular forms of LOD scores and some forms of the maximum-likelihood score statistic (MLS) (Risch, 1990; Knapp *et al*., 1994). It has also been shown that in the presence of locus heterogeneity, this MLS statistic under Holmans' possible triangle constraints (Holmans, 1993) is locally equivalent to the heterogeneity LOD score assuming a recessive trait model (HLOD/R) and that the one-parameter MLS assuming no dominance variance is locally equivalent to a recessive model LOD score assuming homogeneity (Huang and Vieland, 2001).

Misspecification of the trait model in parametric linkage analysis has been given as the motivating reason for use of nonparametric methods. The genetic model can be misspecified in various ways, with varying effects on the outcome of the tests. First, the penetrance functions (including dominance effects) can be specified incorrectly for a qualitative trait or the dominance effects on the genotypic means and variances can be incorrectly specified for a quantitative trait. Incorrectly specifying the dominance relationships among the trait genotypes can result in substantial decreases in power, as can ignoring the possibility of nonpenetrant susceptibility allele carriers or sporadic cases (for dichotomous traits). For qualitative traits, it has been shown that essentially equivalent power can be obtained when using a nonparametric affected-pair linkage test (NPL score) or by using two parametric models, one dominant and one recessive, both allowing 50% penetrance in the susceptible genotypes and adjusting the maximum LOD score by 0.3 LOD units for the multiple testing. This latter method, termed the MMLS-C, has been shown to be both powerful and robust under a variety of complex modes of inheritance including two-locus additive and heterogeneity models (Abreu *et al*., 1999). Variations of this approach include the Mod score, in which the LOD score is maximized over both the recombination fraction and the disease-model parameters (Clerget-Darpoux *et al*., 1986) and the MLOD (Sham *et al*., 2000), in which the LOD score is maximized over the recombination fraction and over the trait-model parameters with the constraint that the penetrances must result in a given population morbid risk and that they are fully dominant or fully recessive. The MOD score has the problem that its sampling distribution under the null hypothesis is uncertain. The MLOD has been shown to have similar power to the NPL score in affected relative

pairs (and not much lower power than that of a LOD score analysis performed under the assumption of the correct genetic parameters) in a variety of situations when there is genetic homogeneity (Sham *et al*., 2000).

The genetic model for the trait may also be misspecified by assuming a single trait locus when in fact multiple loci exist. Both parametric and nonparametric methods that do not make specific allowances for multiple loci can lose power in this situation. LOD scores assuming heterogeneity (HLODs) are more powerful than LOD scores assuming homogeneity in this situation. For quantitative traits, nonparametric tests have been shown to be powerful in the detection of linkage in the presence of heterogeneity, although this power is generally lower than that of appropriate HLODs. For qualitative traits, the MMLS test has also been shown to be more powerful than some nonparametric tests, such as the NPL, in the presence of locus heterogeneity (Abreu *et al*., 1999). However, the power of some nonparametric methods, such as the NPL score, is not greatly reduced from that of the HLOD, MMLS, and MLOD in some situations in which only affected pairs are used in the tests. Thus, the relative power of these parametric and nonparametric methods for qualitative traits often depends on whether unaffected as well as affected relatives are available for study and whether the diagnosis of "unaffected" provides good information on the likely genotype at the susceptibility locus. Although it is possible to devise nonparametric scoring functions that utilize information not only on the sharing of alleles among affected individuals but also on the discordance of sharing between affected and unaffected individuals and on the sharing of alleles among unaffected individuals, many of the commonly used software packages that allow rapid calculation of multipoint nonparametric linkage statistics do not provide such scoring functions as an option. Thus, at least some of the apparent discrepancies in the literature in the relative power of parametric and nonparametric linkage methods may reflect differences in the ability of the particular implementations of these methods to utilize information on unaffected individuals in families.

When considering the application of parametric versus nonparametric tests of linkage, the availability of estimates of the recombination fraction, θ, and the proportion of families linked to the marker locus under consideration, α, are often cited as advantages of parametric tests. For the analysis of simple Mendelian disorders with 100% penetrance, no phenocopies, and a known mode of inheritance, this is a reasonable interpretation of the biological meaning of these mathematical parameters of the models. However, for complex traits with incomplete penetrance, phenocopies, multiple trait loci, and possibly incorrectly specified dominance relationships, these mathematical parameters of the models cannot be so simply interpreted. If one attempts to interpret them thus, one finds that they give biased estimates. In fact, the estimate of θ is a measure of cosegregation of genotypes of a marker locus and inferred genotypes of a trait locus conditional on an assumed model. In any multifactorial trait, the model can never accurately reflect the truth and, therefore, the estimate of θ is not an accurate estimate of the recombination fraction (Goring and Terwilliger, 2000a,b). Similarly, estimates of α are generally biased when HLODs are calculated for complex traits because this parameter is actually the prior probability that the marker will show a given correlation structure in a given family, where that correlation structure is defined by the model and the estimate of the

recombination fraction (Goring and Terwilliger, 2000a; Vieland and Logue, 2002). Thus, we can use HLODs (and MMLS versions of HLODs) as valid tests of linkage for complex traits that may be as powerful or more powerful than nonparametric tests, but we should refrain from interpreting the estimates of θ and α obtained in these analyses as accurate estimates of the recombination fraction or as the estimate of proportion of linked families. These "advantages" of parametric methods over nonparametric methods are not truly useful in the case of complex traits.

3. Two-point versus multipoint linkage

In general, linkage between a trait and a single marker locus (two-point linkage) is less powerful than linkage between a trait locus and a map of multiple marker loci (multipoint linkage) (Fisher, 1954; Lathrop *et al.*, 1985). Multipoint linkage combines the information on the transmission of a haplotype of alleles at nearby loci to better track the transmission of alleles from parents to children in each mating at each location along a chromosome. This can result in large gains in power. However, multipoint linkage requires additional assumptions that are not made in two-point linkage; that is, one assumes that the order and intermarker distances are known without error (Ott, 1999). Multipoint linkage evaluates the probability that a trait locus is located at various places along this known marker map, and thus all multipoint linkage statistics test for linkage with a 0 recombination fraction to a certain location on the map. In two-point parametric linkage, as discussed above, misspecification of the trait model may result in the inflation of the estimate of the recombination fraction, with some loss of power to detect linkage (Ott, 1999). However, this inflation of the estimate of the recombination fraction is not possible in multipoint parametric linkage, so any misspecification of the trait model, including heterogeneity, tends to decrease power to detect linkage more strongly than in two-point linkage. It is very important to allow for the possibility of genetic heterogeneity in multipoint parametric linkage analysis. In addition, misspecification of the marker map order or (to a lesser extent) intermarker distances will also decrease power to detect linkage in both parametric and nonparametric multipoint linkage (Ott and Lathrop, 1987; Ott, 1999), but these problems are not relevant to two-point linkage. Therefore, most analysts perform both two-point and multipoint linkage analyses on their data, and compare the results carefully. It is also important to estimate marker allele frequencies from the data to be analyzed, analyze separate ethnic groups that may have different allele frequencies separately, obtain the best genetic maps possible for marker loci, check for evidence of excessive double recombinants between markers since this may indicate incorrect map specification, and if necessary drop marker loci that are not well mapped.

Specialist Review

Gene mapping, imprinting, and epigenetics

Konstantin Strauch
University of Bonn, Bonn, Germany

1. Introduction

Genomic imprinting, which is also called parent-of-origin effect, is an important epigenetic factor that leads to complete or partial deactivation of either the paternally or maternally inherited copy of a gene (*see* Article 26, **Imprinting and epigenetic inheritance in human disease**, Volume 1). For example, if a disease gene is subject to complete maternal imprinting, individuals who are heterozygous at the disease locus express the trait if they have inherited the mutant allele from the father, but do not do so if they have received it from the mother. Maternal imprinting is therefore equivalent to paternal expression. With imprinting, the penetrance depends on the sex of the parent who transmits a certain allele, rather than the sex of the individual who receives the allele. It should be noted that imprinting needs to be distinguished from other parental effects such as maternal-fetal interactions. Imprinting is determined by chromosomal region (see e.g., Hall, 1990; Ainscough and Surani, 1996; Bartolomei and Tilghman, 1997; Reik and Walter, 2001). Two mechanisms known to be involved in the process of imprinting are DNA methylation (*see* Article 32, **DNA methylation in epigenetics, development, and imprinting**, Volume 1) and the differential packing density of DNA by histone proteins (*see* Article 27, **The histone code and epigenetic inheritance**, Volume 1). Evolutionary causes that have led to the establishment of imprinting were discussed by Pardo-Manuel de Villena *et al*. (2000), de la Casa-Esperón and Sapienza (2003), as well as by Wilkins and Haig (2003) (*see* Article 37, **Evolution of genomic imprinting in mammals**, Volume 1). Beckwith–Wiedemann, Prader–Willi, and Angelman syndromes are examples of rare disorders that show a parent-of-origin effect (Falls *et al*., 1999; *see also* Article 29, **Imprinting in Prader–Willi and Angelman syndromes**, Volume 1 and Article 30, **Beckwith–Wiedemann syndrome**, Volume 1). Imprinting is also known or suspected to play a role in many complex traits as well, including type I diabetes (Bain *et al*., 1994; Paterson *et al*., 1999), polycystic ovarian syndrome (Bennett *et al*., 1997), atopy (Daniels *et al*., 1996; Moffatt and Cookson, 1998; *see also* Article 61, **Allergy and asthma**, Volume 2), celiac disease (Petronzelli *et al*., 1997), preeclampsia (Esplin *et al*., 2001), cancer (Falls *et al*., 1999; *see also* Article 65, **Complexity of cancer as a genetic disease**, Volume 2), epilepsy

(Greenberg *et al*., 2000), or bipolar disorder (Stine *et al*., 1995; McInnis *et al*., 2003).

2. How can imprinting be accounted for in the context of linkage analysis?

In order to model a parent-of-origin effect, it is necessary that parent-specific genotypes are available, or otherwise can be reconstructed, such as with half-sibs. This holds for parametric and nonparametric linkage analysis of dichotomous traits, as well as for an analysis of quantitative traits.

2.1. *Parametric analysis*

In the simplest case of a dichotomous trait that is governed by one locus, the trait model comprises the disease allele frequency and three penetrance parameters $\{f_{+/+}; f_{Het}; f_{m/m}\}$, that is, the probabilities to express the trait, given one of the three possible genotypes. Here, "+" and "*m*" refer to the wild-type and mutant allele, respectively, and "Het" stands for the heterozygous genotype. Usually, a linkage analysis represents the first step toward the mapping of a disease gene whose location is unknown. In the context of a parametric (model-based) linkage analysis, the disease allele frequency and penetrances have to be specified prior to the analysis. When performing linkage analysis of imprinted disease genes, however, the three-penetrance formulation is insufficient. In this case, the probability that a heterozygote expresses the trait is greatly influenced by the parent who transmitted the disease allele. Let us look at the example of a fully penetrant disease allele with no phenocopies and complete maternal imprinting, that is, exclusively paternal expression. If the specified heterozygote penetrance is 0, heterozygotes who have inherited the mutant allele from the mother will be treated correctly, whereas for those heterozygotes who have inherited the disease allele from the father, the parameter will be wrong. Likewise, if the heterozygote penetrance is specified to be 1, heterozygotes who have inherited the disease allele from the father will be treated correctly, but not those who have inherited the disease allele from the mother. Hence, no matter what heterozygote penetrance is specified for the analysis, it will not be optimal for the mapping of imprinted genes.

In a linkage study of bipolar affective disorder, Stine *et al*. (1995) classified the pedigrees according to "maternal" and "paternal" transmission of the disease, and performed separate linkage analyses for the two classes. Substantial differences between the LOD scores for the "maternal" and "paternal" pedigrees were interpreted as evidence for imprinting. However, such a classification does not make sense if the disease is transmitted through both males and females. As an alternative, it has been proposed to use sex-specific recombination fractions between marker and trait locus for the calculation of LOD scores (Smalley, 1993), or to fix the recombination fraction of the imprinting sex at 1/2. This allows for an explanation of unaffected heterozygotes by fictitious recombinations in the parent who has transmitted the mutant allele. It is also possible to define separate liability

classes for heterozygotes who have inherited the disease allele from the father and from the mother (Heutink *et al*., 1992). Still, in most cases, it is impossible to infer the parent-of-origin at first sight; it can only be inferred by likelihood calculation. Thus, the most natural approach to account for imprinting in the context of a parametric linkage analysis is to extend the trait model to contain two different heterozygote penetrances, one for paternal and one for maternal origin of the disease allele. This allows for flexibly taking the parent-of-origin into account in the likelihood calculation, by use of the appropriate penetrance. Altogether, the trait model with imprinting contains four penetrance parameters. This formulation was implemented into the program GENEHUNTER-IMPRINTING (Strauch *et al*., 2000a), which, in its current version, is based on the original GENEHUNTER v2.1 (Kruglyak *et al*., 1996; Kruglyak and Lander, 1998; Markianos *et al*., 2001). The program employs the Lander–Green algorithm (Lander and Green, 1987) and can therefore easily cope with a large number of markers (*see* Article 52, **Algorithmic improvements in gene mapping**, Volume 1). On the other hand, pedigrees are restricted to be of moderate size. Version 2 of the program VITESSE (O'Connell and Weeks, 1995; O'Connell, 2001) can also take imprinting models with four penetrances into account. This program mainly uses the Elston–Stewart algorithm (Elston and Stewart, 1971) (although version 2 also incorporates features of the Lander–Green algorithm); therefore, it can handle larger pedigrees, but there is a limit on the number of markers that can be jointly analyzed. In terms of significance, LOD scores obtained under a four-penetrance model are directly comparable to LOD scores obtained under a three-penetrance nonimprinting model, provided that a single predefined model is used. However, this no longer holds if the LOD scores are maximized not only over the recombination fraction between marker and trait locus (or, in the context of multimarker analysis, over the genetic map position of the trait locus) but also with respect to the disease allele frequency and penetrances, as is done in a MOD-score analysis (Clerget-Darpoux *et al*., 1986).

It should be expected that the power to detect linkage for imprinted genes is higher under a four-penetrance imprinting model than it is under a standard trait model with three penetrances. Indeed, this is the finding obtained by Strauch *et al*. (1999). The result can be anticipated when looking at the diamond of inheritance (DOI), which is shown in Figure 1, for the special case of complete penetrance and no phenocopies. The DOI illustrates the parameter space formed by the two heterozygote penetrances of the four-penetrance imprinting model. The penetrances are given in the order $\{f_{+/+}; f_{m/+}; f_{+/m}; f_{m/m}\}$, with the paternally inherited allele listed first. In order to obtain a more instructive illustration of the relationships between different modes of inheritance (MOI), the two heterozygote penetrances $f_{m/+}$ and $f_{+/\mathrm{m}}$ are transformed into the dominance index D and the imprinting index I. These two values were previously defined in the context of Figure 1 in Strauch *et al*. (2000a). Here, in order to properly take the case of a nonzero phenocopy rate or reduced penetrance into account, the dominance and imprinting index are redefined as follows:

$$D = \frac{f_{m/+} + f_{+/m} - f_{+/+} - f_{m/m}}{f_{m/m} - f_{+/+}} \qquad I = \frac{f_{m/+} - f_{+/m}}{f_{m/m} - f_{+/+}} \tag{1}$$

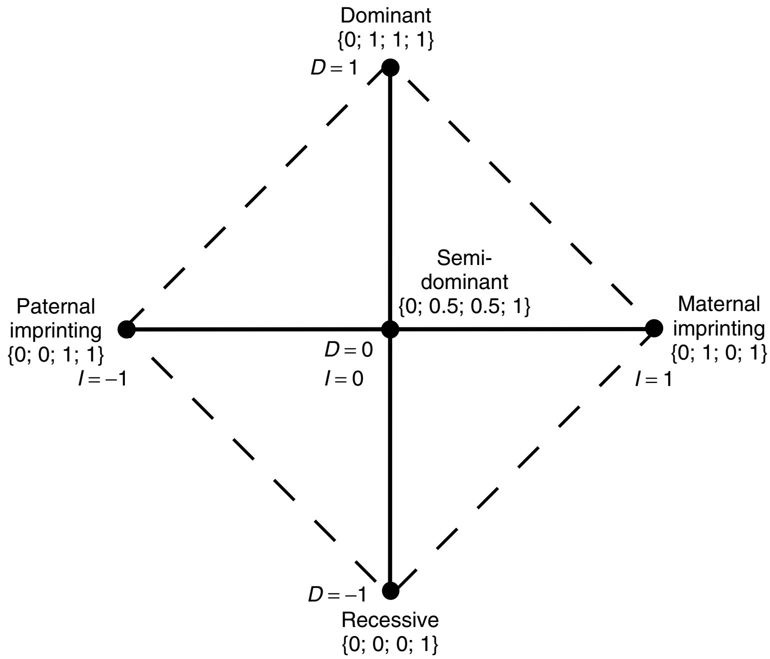

Figure 1 The diamond of inheritance visualizes the parameter space formed by the two heterozygote penetrances of the four-penetrance trait model that takes genomic imprinting into account, for the special case of no phenocopies and complete penetrance (i.e., $f_{+/+} = 0$ and $f_{m/m} = 1$). Dominant ($D = 1$), semidominant ($D = 0$), and recessive modes of inheritance ($D = -1$) are shown on the vertical axis, with the degree of imprinting I being 0. For these models, the heterozygote penetrances $f_{m/+}$ and $f_{+/m}$ are equal. A trait model on the left half of the diamond, with $f_{m/+} < f_{+/m}$ and $I < 0$, corresponds to paternal imprinting. Analogously, a model on the right half of the diamond, with $f_{m/+} > f_{+/m}$ and $I > 0$, corresponds to maternal imprinting. (Modified from Strauch K, Fimmers R, Kurz T, *et al*. Parametric and non-parametric multipoint linkage analysis with imprinting and two-locus-trait models in the *American Journal of Human Genetics*, 2000; **66**, 1945–1957, with permission)

The dominant and recessive MOI are the distal points on the vertical dominance axis, with the dominance index D ranging from -1 (recessive MOI, both heterozygote penetrances equal $f_{+/+}$) to 1 (dominant MOI, both heterozygote penetrances equal $f_{m/m}$). For a semidominant or additive MOI, the two heterozygote penetrances are halfway between the two homozygote penetrances $f_{+/+}$ and $f_{m/m}$, and D equals zero. All nonimprinting models, for which the two heterozygote penetrances are equal (i.e., $I = 0$), are represented by the central vertical line. The imprinting axis is perpendicular to the dominance axis; the imprinting index I ranges from -1 (complete paternal imprinting) to 1 (complete maternal imprinting). In these extreme cases of complete imprinting, one heterozygote penetrance equals $f_{+/+}$ and the other equals $f_{m/m}$. Figure 1 shows the diamond of inheritance with these new definitions of D and I. The graphical representation clearly illustrates that the paternal- and maternal-imprinting MOI lie far off the central axis of dominant–recessive inheritance. It explains the fact that the power to detect

linkage will drop if imprinting is not adequately accounted for in the analysis. This is equivalent to the statement for standard LOD-score analysis under three-penetrance trait models that the power to detect linkage is maximal if the analysis model roughly equals the true disease model (Clerget-Darpoux *et al*., 1986).

2.2. Nonparametric analysis

It is also possible to account for genomic imprinting in a nonparametric or model-free linkage analysis. Paterson *et al*. (1999) and McInnis *et al*. (2003) proposed to evaluate allele sharing separately for male and female meioses. Significant differences point to an imprinted gene. An option to perform such an analysis has been implemented into the program ASPEX (Hinds and Risch, 1996), in which two different χ^2 tests with 1 degree of freedom are performed, one each for sharing by male and female meioses. In a linkage study of psoriatic arthritis, Karason *et al*. (2003) used imprinting-based scoring functions, for nonparametric analysis of extended pedigrees, which have been implemented into the program ALLEGRO (Gudbjartsson *et al*., 2000). In particular, weights to allele sharing are assigned specific to parental origins. For example, the scoring function considers only the sharing of alleles transmitted to two affected relatives through their mothers, if paternal imprinting is to be modeled. Knapp and Strauch (2004) have developed a likelihood-based affected sib-pair test for imprinted disease genes. It is similar to Holmans' possible triangle test (Holmans, 1993), for the nonimprinting case, which is an extension of the likelihood-ratio test proposed by Risch (1990). In the approach taken by Knapp and Strauch, affected sib pairs who share one allele identical-by-descent (ibd) are distinguished by whether sharing is through the mother or father. Constraints on the sharing probabilities are derived for genetically possible models, which may include imprinting, similar to Holmans' triangular constraints for the nonimprinting case. The corresponding likelihood-ratio test proves to be substantially more powerful than Holmans' possible triangle test in the case that imprinting is present, at the cost of only a small reduction in power if there is no imprinting.

2.3. Quantitative trait locus analysis

Linkage analysis methods that adequately take imprinting into account also exist for quantitative trait loci (QTL). In the context of nuclear families, such methods were proposed by Hanson *et al*. (2001), for variance components analysis and Haseman–Elston regression, as well as by Shete and Amos (2002), for variance components analysis. Here, the proportion of alleles shared ibd is partitioned into a component derived from the father and a component derived from the mother. A further development of variance components analysis with imprinting for extended pedigrees has been described by Shete *et al*. (2003). In that context, allele-sharing ibd by two relatives is distinguished by the combination of sexes of the two transmitting parents.

3. Tests for linkage versus tests for imprinting

It is important to distinguish between tests for linkage that take imprinting into account and tests for imprinting per se. For example, a parametric analysis under a four-penetrance trait model represents a test for linkage that accounts for imprinting. However, a LOD-score analysis under such an extended trait model can also be used to infer the degree of imprinting, by calculation of MOD scores (i.e., maximization of the LOD score with respect to the disease-model parameters) (Strauch *et al*., 2000a). A difference between the two heterozygote penetrances $f_{m/+}$ and $f_{+/m}$ of the best-fitting model obtained by MOD-score analysis may indicate a parent-of-origin effect. To judge whether imprinting is indeed present, one can look at the difference between MOD scores obtained for analysis under models with and without imprinting (i.e., with four and three penetrances, respectively). The method employed by Paterson *et al*. (1999) and McInnis *et al*. (2003) allows for an investigation of linkage in the presence of imprinting, when looking at the allele sharing for male and female meioses. It can also be used to test for imprinting, when focusing on the difference between sharing for male and female meioses. The imprinting-based scoring functions for nonparametric analysis, used by Karason *et al*. (2003), can as well be used to test both for linkage and imprinting. For an assessment of linkage, one has to look at the results obtained for the paternal-imprinting and maternal-imprinting scoring functions, and for imprinting, one has to focus on their difference. The likelihood-based test proposed by Knapp and Strauch (2004) is a test for linkage that accounts for imprinting. In addition, a likelihood-based affected sib-pair test for imprinting is outlined in the discussion section of that paper. The latter is equivalent to a test for imprinting proposed by Olson and Elston (1998). The methods for QTL analysis developed by Hanson *et al*. (2001), Shete and Amos (2002), and Shete *et al*. (2003) allow for both the assessment of linkage under imprinting and the assessment of imprinting.

4. Confounding between imprinting and sex differences in recombination fractions

Researchers need to be aware of the fact that imprinting can be confounded with sex differences in recombination fractions. As described above, it is possible to use sex-specific recombination fractions to allow for imprinting in a linkage analysis (Smalley, 1993). In that approach, unaffected heterozygotes are accounted for by excess recombinations in the sex whose transmitted allele is imprinted. On the other hand, it is also possible that a true sex difference in recombination fractions is misinterpreted as evidence for imprinting, in cases in which actually no genomic imprinting is present. For example, if the recombination fraction in a certain genetic region is higher in females than in males, the additional recombinations in females can be explained by a maternal-imprinting model in the context of a parametric analysis. By this means, the additional female recombinations are regarded as nonexistent, and the appearingly transmitted disease alleles from the mother are interpreted as being nonpenetrant. This confounding also occurs with

nonparametric linkage analysis. In the case of sex differences in recombination fractions, the excess allele sharing, due to an existing linkage, will be smaller for the alleles inherited from the parent who has a higher recombination fraction between marker and trait locus. The smaller amount of allele sharing through this parental sex will be interpreted as imprinting. In order for an imprinting analysis to be robust with respect to sex differences in recombination fractions, Paterson (2000) proposed to perform multimarker analysis with sex-specific maps (*see* Article 54, **Sex-specific maps and consequences for linkage mapping**, Volume 1). However, it can be argued that confounding does not represent a major problem in the context of multimarker analysis, even if sex-averaged recombination fractions are used (Strauch *et al*., 2000b). Here, each genetic position within the marker group is located between two flanking markers. In this situation, it is hardly possible to use fictitious recombinations to explain carriers of the disease allele who are unaffected because of imprinting. This is because such fictitious recombinations would have to be double recombinations, which are rather unlikely. By the same token, a truly existing sex difference in recombination fractions may lead to additional recombinations, in the meioses of one sex, between a putative disease-locus position and one marker, but not with both flanking markers at the same time. This will remove the advantage of an analysis method that accounts for imprinting, over one that does not, since it is no longer necessary to explain a recombination by a nonpenetrant case. However, these arguments no longer hold if the sex ratio of the recombination fractions takes extreme values in a particular genetic region, or if the marker density is low. In such a case, double recombinants are possible, and confounding becomes likely. However, the problem of double recombinants cannot be remedied by use of sex-specific marker maps; rather, additional markers should be typed in order to increase marker density. This is not only important to avoid confounding, but also to increase linkage information, which is otherwise going to be low for the meioses of the sex with the higher recombination fractions.

5. Imprinting and association analysis

The basic idea common to all imprinting association methods is to distinguish between maternally and paternally transmitted alleles when investigating an influence on the trait. For this reason, it is not possible to model a parent-of-origin effect in case–control association studies, and thus, family-based designs are a prerequisite. In the context of dichotomous traits, Weinberg *et al*. (1998) proposed a log-linear method, allowing researchers to perform a likelihood-ratio χ^2 test for association that takes imprinting into account. With this method, it is also possible to estimate association parameters, such as relative risks, and to test for imprinting itself. Furthermore, they devised a "transmission asymmetry test", in the spirit of the transmission/disequilibrium test (TDT), which also is a test for imprinting. Weinberg (1999) reviewed association methods for detection of imprinting, and showed that they can be invalid under certain scenarios. This holds, for example, for a stratification of the transmission/nontransmission counts by the parental sex if the sample includes case-parents triads with two heterozygous parents. In addition, problems can arise in the case of maternal effects. Therefore, in the same work,

Weinberg proposed two new methods, based on a logistic model that includes the parental mating type as well as the number of inherited copies of the allele under study. Methods of association that account for imprinting in the context of quantitative traits were described by van den Oord (2000), who proposed to use a finite mixture model, and by Whittaker *et al*. (2003), who employed simple linear models. For association analysis in general, confounding between sex differences in recombination fractions and imprinting should not represent a problem, since association will usually only be detected for markers tightly linked to a disease locus.

6. Conclusion

It is well known that a considerable portion of the human genome is subject to imprinting (Hall, 1990). However, not all imprinted genetic regions have been identified and localized yet. Since the power to detect imprinted genes will be highest if a parent-of-origin effect is adequately accounted for in the analysis, researchers should routinely employ methods that model imprinting, for both linkage and association analysis. This holds particularly for genetically complex diseases, for which the effect of a single gene on the trait is likely to be small. If genetic mapping studies in the past did not show positive results, it may, therefore, be reasonable to reanalyze the data with a method that accounts for imprinting. During the past years, a considerable number of methods and computer programs for analysis have been developed that take parent-of-origin effects into account. It is likely that they will contribute to the mapping of imprinted genes responsible for both Mendelian and complex traits.

Specialist Review

Gene mapping and the transition from STRPs to SNPs

Ellen M. Wijsman
University of Washington, Seattle, WA, USA

1. Introduction

Human gene mapping is focused on two major goals. The first is linkage detection: to determine where, relative to a genetic map, gene(s) are located that contribute to the trait. The second goal is localization: to more accurately determine the location of the gene(s), in preparation for gene identification. Although these goals have not changed, the types of markers used to achieve these goals have changed over time.

The principles behind gene mapping in humans are identical to those for other diploid organisms. However, there are numerous practical complications. Meioses used in gene mapping are not observed directly, but are inferred through examination of genetic markers in pedigrees. In human pedigrees, the inability to control matings leads to the use of indirect statistical methods for inference regarding meiotic transmission. In addition, the need to use observational data has two important implications. First, the sample sizes and the cost of human studies are high, because the loss of information in uncontrolled crosses leads to the need for increased sample sizes, and identification of pedigrees with ideal characteristics for gene mapping can be difficult and labor-intensive (*see* Article 57, **Genetics of complex diseases: lessons from type 2 diabetes**, Volume 2). Second, it is necessary to develop procedures that result in reliable and efficient extraction of mapping information on arbitrary pedigrees since pedigree structures vary widely (*see* Article 60, **Population selection in complex disease gene mapping**, Volume 2). These two issues create the need to search for approaches that maximize the use of available data.

The development of efficient human gene mapping studies involves interrelated areas, each of which will be discussed in more depth, below. An understanding of changes in mapping procedures in response to a move from STRPs (single tandem repeat polymorphisms) to SNPs (single-nucleotide polymorphism) requires an understanding of each of these areas, and how it interacts with the choice of the marker. The areas are as follows: (1) The choice of genetic marker has changed over time. The transition evolved from classical protein-based markers to the early DNA-based restriction fragment length polymorphisms (RFLPs), which were typically diallelic, to multiallelic variable number tandem repeat (VNTR) and finally to microsatellite STRPs. With each transition, automation and speed of

genotyping increased, as did the mapping information achievable. Costs dropped. More recently, the use of SNPs has been proposed, on the basis of high speed and low cost, which is potentially achievable. (2) Construction of the associated genetic maps involves the consideration of possible analysis approaches, and potential data. Both the density and the structure of such maps are relevant, as is the quality of the map estimates. (3) There is an ever-growing arsenal of approaches to analysis, with an increasing emphasis on the development of statistical methods suitable for complex traits. Depending on other aspects of the data and analysis, there are often constraints on either the number of markers that can simultaneously be used in the analysis or on the sizes of pedigrees that can be analyzed. (4) Finally, the choice of pedigrees selected for a study interacts with the analytical approaches and with the number of markers and map structure that is practical to use in analysis.

2. Genotyping technologies

Marker genotyping technologies have changed considerably over time (*see* Article 77, **Genotyping technology: the present and the future**, Volume 4). The realization that DNA-based variation could provide an essentially limitless source of markers was a breakthrough (Botstein *et al*., 1980). Prior to this, identifying new markers involved serendipity, and large-scale genotyping was extremely expensive. DNA-based variation, on the other hand, can be assayed with generic methods, and the use of RFLPs, which were the first DNA-based markers, resulted in rapid growth in the number of mapped markers (Dib *et al*., 1996). Early DNA genotyping was still expensive, thus severely limiting the sizes of the studies that could be tackled and thus the complexity of the traits that could be analyzed with reasonable cost. In addition, the diallelic polymorphisms that were typical of RFLPs were relatively uninformative for gene mapping.

The success of RFLPs stimulated the development of better markers and identification and popularization of STRPs (Weber and May, 1989). STRPs have long remained the most popular type of markers, serving well for simple and complex traits, as well as for analysis of large and small pedigrees (*see* Article 67, **History of genetic mapping**, Volume 4). STRP genotyping has modest costs because of considerable automation, but rapid genotyping is achieved only in the largest facilities. Recently, SNPs have been proposed as a replacement (Hastbacka *et al*., 1992; Kruglyak, 1997), with the expectation that use of large numbers of SNPs can be used to offset the lack of mapping information intrinsic in diallelic markers, and that genotype scoring can be almost completely automated, thus increasing the speed and reducing the costs. However, in considering the transition to SNPs, it is useful to remember the four major reasons leading to the popularity of STRPs (*see* Article 67, **History of genetic mapping**, Volume 4). (1) STPRs provide high information for mapping (*see* Article 53, **Information content in gene mapping**, Volume 1) even in single-marker analysis. (2) STRPs are applicable to a wide variety of problems and data sets. (3) STRPs can be used for most analytical approaches (*see* Article 48, **Parametric versus nonparametric and two-point versus multipoint: controversies in gene mapping**, Volume 1), with relative

insensitivity to simplifying assumptions in analysis. (4) With STRPs, the genotyping component of a study represents a relatively low fraction of the total cost of a study, including pedigrees and phenotype collection, genotyping, and analysis.

3. Information

A critical factor is the information obtained. Here, we describe two aspects of information (*see* Article 53, **Information content in gene mapping**, Volume 1) that are relevant in the comparison of STRP- and SNP-based mapping studies. First, there is the fraction of *mapping information*, or I_m, measured on a scale of 0 to 1, that can be extracted via a particular marker set. Second, there is the *total information*, I_t, potentially available in a pedigree data set. Such information increases with increasing sizes of data sets (*see* Article 51, **Choices in gene mapping: populations and family structures**, Volume 1), and is a function of aspects of the data such as number and sizes of pedigrees, as well as the phenotype. Finally, the combination gives the *realized information*, or I_r, where $I_m I_t = I_r$. The amount of data needed is a function of I_r. Clearly, the design of a study is a function of the information that can be extracted with a particular panel of markers, relative to the maximum that could be extracted with perfect markers, and the underlying absolute amount of information potentially available in a data set.

Information is most usefully defined in the context of a particular analytic method. The different measures of mapping information will not give identical results when applied to a particular set of markers in a particular data set. Examples of mapping information measures that are based on particular analytic frameworks are PIC (Botstein *et al*., 1980), which is a useful measure for methods that are based on scoring transmitted gametes, MPIC (Goddard and Wijsman, 2002), which is an extension to tightly clustered markers, and LIC (linkage information content) (Guo and Elston, 1999), which is useful for methods based on identity-by-descent (ibd) sharing in pairs of individuals. Another information measure is that of entropy, which has been proposed as a general measure of information for use in evaluating information in multilocus maps (Kruglyak, 1997). This measure, while strongly correlating with other measures, is not a direct measure of mapping information that is achieved with any particular method of linkage analysis. Each measure of information describes the proportion of meioses or other sampling units (e.g., sib pairs) that can be scored for the event of interest, assuming accuracy of all aspects of the map and marker model. For a particular measure, a value of $I_m = 0.5$ requires a doubling in sample size to achieve the same realized sample size as would $I_m = 1$. Investigators generally desire high values for I_m since for a particular choice of pedigree type and analytic approach (dictating I_t), this minimizes the necessary sample size collected.

High I_r can be achieved by using individual STRPs, by using multiple markers, or by a combination of strategies (*see* Article 53, **Information content in gene mapping**, Volume 1). Increased marker density increases I_m when used in multipoint analysis, as does an overall increase in the number of markers. Multipoint analysis is essential for the realization of high information in the context of SNP marker scans. In contrast, although it can improve the available information,

it is not always absolutely necessary for analysis with STRPs. Simulation studies demonstrate that even for STRPs at typical mapping densities, I_m increases considerably when multiple markers are used in multipoint analysis (Amos *et al*., 1997), and similar studies have shown that high values for I_m are obtainable for panels of SNP markers (International Multiple Sclerosis Genetics Consortium, 2004; John *et al*., 2004; Matise *et al*., 2003). There are also proposals for different ways to construct SNP multipoint mapping panels that end up with information that is at least as high as the information obtainable with STRPs. These include the use of SNP panels with a uniform marker density (Kruglyak, 1997) as well as the use of SNP mapping panels that are based on clusters of very closely linked SNPs (see Section 6) (Goddard and Wijsman, 2002).

It is I_r that is important in a mapping study. When discussing issues pertaining to the choice of STRP versus SNP markers for linkage analysis, there is a tendency to focus only on I_m. The pedigree and trait material used for analysis (*see* Article 51, **Choices in gene mapping: populations and family structures**, Volume 1 and Article 60, **Population selection in complex disease gene mapping**, Volume 2) are as important since this determines, in part, the pedigrees collected, which affects I_r. While I_m can increase by 30–40% for STRP markers with the use of multipoint instead of single-marker analysis, I_t can easily increase by 200–300% per sampled individual, when appropriate choice of pedigrees and/or phenotypes are considered (Wijsman and Amos, 1997). The part of a gene mapping study that is the slowest and most expensive is the collection of the pedigree and phenotype data. It may be overall most effective in many cases to collect pedigree and phenotype data that has maximum I_t per sampled individual, and then to use analysis methods that use these data most efficiently. This may have important ramifications in the choice of a marker panel.

4. Experience with real data

To date, there have been only a few reports describing the use of SNPs in linkage analysis of real data. Information about the performance of SNPs for use on real data will undoubtedly change soon, since multiple data collections and analyses are currently in progress. Real-life experience with SNPs will be needed to identify the problems that almost certainly will occur as investigators gain experience with the use and analysis of data derived from SNP marker panels.

Analyses on real data sets that have been typed for both STRP and SNP markers support the theoretical prediction that information estimated on these data sets increases with marker density (*see* Article 53, **Information content in gene mapping**, Volume 1). Computed information is greater for sufficiently dense panels of SNP markers than that for standard 10-cM density panels of STRP markers (International Multiple Sclerosis Genetics Consortium, 2004; John *et al*., 2004), and increases with the density of SNP marker panels (International Multiple Sclerosis Genetics Consortium, 2004). Note that these conclusions are based on the assumption that the model used to compute information in a multipoint setting is sufficiently close to correct, including the marker allele frequencies, linkage equilibrium between markers, genetic map distances, and mapping function

(*see* Article 68, **Normal DNA sequence variations in humans**, Volume 4). We do not yet know how robust these assumptions are. However, there are suggestions that there may be inaccuracies in the model used to predict information in multipoint analysis. There are regions with substantial differences in the information computed for SNP versus STRP panels, yet the linkage analysis provided virtually identical results (Browning *et al*., 2004; John *et al*., 2004). In other regions, information in two marker panels was nearly identical, but the linkage signals were substantially different (Browning *et al*., 2004). Until these discrepancies are understood, caution is needed in interpreting the measures of information used to compare multipoint SNP versus STRP mapping panels.

For the one published comparison of genome scan results for a large nuclear-family data set with ∼10 000 SNPs and ∼400 STRPs, there was overall excellent agreement in the results obtained with both marker panels (John *et al*., 2004). In this study, the most convincing evidence for linkage was stronger for the analyses with STRPs than for that obtained with the SNPs, despite higher computed regional marker information for the SNPs. There were also several additional regions with virtually identical but modest linkage signals; with a few modestly higher for the SNPs and others for the STRPs. It is difficult to make definitive statements regarding the advantages or disadvantages of the use of either of the mapping panels, on the basis of these results.

5. Linkage analysis

5.1. *Analysis basics*

The choice of marker panel presents several issues. One can choose to use single-marker or multipoint analysis, and an analysis method based on marker ibd-sharing or one based on an explicit or estimated trait model (e.g., parametric LOD score or joint linkage and segregation analysis) (*see* Article 48, **Parametric versus nonparametric and two-point versus multipoint: controversies in gene mapping**, Volume 1 and Article 56, **Computation of LOD scores**, Volume 1). The rationale for the choice of a strategy is best determined by the trait to be mapped, estimates of power to detect linkage under various analysis scenarios and marker choices, and the goal(s) of the analysis. For example, in cases of trait model misspecification, parametric linkage analysis with single markers may have higher power for linkage detection than would a multipoint analysis (Risch and Giuffra, 1992; Sullivan *et al*., 2003). A single-marker analysis with a typical STRP may also have higher power to detect linkage than a multipoint analysis with SNPs, if the use of SNPs involves significant pedigree pruning to make the computations feasible. On small pedigrees, a multipoint approach may be feasible and desirable, especially if the analysis is based on an ibd-scoring method. Accurate localization that follows linkage detection may be the primary goal in other studies, in which case a parametric multipoint analysis may be the approach of choice, since ibd-sharing methods, which are, strictly speaking, only linkage-detection methods, give poor information regarding localization regardless of marker density (Atwood and

Heard-Costa, 2003). Because there is no single analytical approach that is optimal for all data sets, there will also probably be no single-marker panel that is also optimal under all conditions.

While STRPs can be efficiently used for both single-marker and multipoint analysis, the use of SNPs *requires* multipoint analysis to maintain reasonable information (*see* Article 53, **Information content in gene mapping**, Volume 1). STRPs can be effectively used for ibd-sharing as well as trait-model-based analyses, with single-marker analysis sometimes preferred (*see* Article 48, **Parametric versus nonparametric and two-point versus multipoint: controversies in gene mapping**, Volume 1). Also, for STRPs there are many statistical approaches available, with computational tools implementing such approaches (*see* Article 52, **Algorithmic improvements in gene mapping**, Volume 1). In contrast, although some of these analytical methods can be used with SNPs, the effect of violation of assumptions underlying the analyses has not been evaluated. The long-term use of SNPs for the wide range of possible problems may need to include additional assumptions and methods. It also needs to include an understanding of assumptions behind the analysis, so that appropriate modifications and extensions to existing approaches can be developed.

5.2. Modifications and extensions needed

Current analysis methods were developed under the assumption of linkage equilibrium among markers (*see* Article 2, **Modeling human genetic history**, Volume 1). For STRP marker panels, which range from 400 to 2000 markers (~10 cM to ~2 cM density), this is a reasonable assumption since linkage disequilibrium (LD) (*see* Article 10, **Measuring variation in natural populations: a primer**, Volume 1 and Article 17, **Linkage disequilibrium and whole-genome association studies**, Volume 3) at such spacing is rare (Dawson *et al.*, 2002; Stephens *et al.*, 2001). In contrast, some SNP panels are sufficiently dense that LD between neighboring markers may affect the analysis (*see* Article 68, **Normal DNA sequence variations in humans**, Volume 4, Article 71, **SNPs and human history**, Volume 4, and Article 73, **Creating LD maps of the genome**, Volume 4). Recent work suggests that the presence of LD among SNPs can lead to inflated evidence of linkage, when an analysis approach that assumes linkage equilibrium is used (Schaid *et al.*, 2004). While a few computer programs, such as FASTLINK (Cottingham *et al.*, 1993; *see also* Article 52, **Algorithmic improvements in gene mapping**, Volume 1), allow for LD among loci, these programs are unsuitable for use with large numbers of markers, as is needed for SNP panels. Alternatives that allow for local LD while handling large numbers of markers are necessary for the use of SNPs.

Multipoint analysis assumes accurate meiotic maps (*see* Article 54, **Sex-specific maps and consequences for linkage mapping**, Volume 1). The pedigrees typically used to construct maps were assembled with relatively sparse maps in mind. Recent construction of denser maps and comparison of sequence-based and meiotic maps has identified discrepancies in map estimates for closely spaced markers (Hattori *et al.*, 2000), providing empirical support for the concern that small map

distances may be unreliably estimated. Statistical arguments predict that there may be somewhat inflated false-positive rates in the presence of map misspecification (Daw *et al*., 2000; *see also* Article 54, **Sex-specific maps and consequences for linkage mapping**, Volume 1). Analysis of real data under a variety of estimated maps has shown that results can be quite sensitive to map distance estimates (Gretarsdottir *et al*., 2002), suggesting that for reliable results from SNP maps, it may be necessary to both develop methods to estimate maps from the combined data across multiple studies and to develop systematic approaches to evaluate sensitivity of conclusions to map assumptions.

Genotyping error may influence linkage analysis results. For STRPs, it is safe to assume low error rates in linkage analysis, since most errors are readily identified (Epstein *et al*., 2000; Sieberts *et al*., 2002). For SNPs, error identification is more difficult, and unidentified errors may be influential (Cherny *et al*., 2001). More effort may be needed in data cleaning, and models that directly incorporate genotyping error models into the linkage analysis may be needed.

Computational algorithms will need modification and development (*see* Article 52, **Algorithmic improvements in gene mapping**, Volume 1). Currently, there are practical constraints on the number of markers that can be used in a linkage analysis, even when the efficient Lander–Green algorithm serves as the basis for computation (Lander and Green, 1987). While there have been improvements (Abecasis *et al*., 2002; Gudbjartsson *et al*., 2000; Kruglyak, 1997; Markianos *et al*., 2001), computation with many hundreds of markers remains challenging, and remains limited to pedigrees of modest size. Other methods of analysis that allow multipoint computation on larger pedigrees, such as Markov chain Monte Carlo (MCMC) approaches (Heath, 1997; Sobel and Lange, 1996; Wijsman, 2003), are also likely to require substantial development to make them practical for use on SNP data. This could be critical since MCMC approaches are among the few that also allow for more complex trait models (Heath, 1997). One fundamental problem is that even the most efficient algorithms increase computation time linearly with the number of markers in the analysis. Although computers steadily increase in speed, it may take a decade for the hardware to catch up with the computational demands of current SNP panels.

6. Maps

There are multiple possible distributions of markers on a map. Uniform marker density provides the maximum information per typed marker (Goddard and Wijsman, 2002; *see also* Article 53, **Information content in gene mapping**, Volume 1). However, in order to realize this information, it is necessary to be able to use all the typed markers in a multipoint analysis. For some data sets, particularly consisting of large pedigrees (*see* Article 51, **Choices in gene mapping: populations and family structures**, Volume 1), multipoint analysis quickly becomes computationally infeasible (*see* Article 52, **Algorithmic improvements in gene mapping**, Volume 1). One compromise that has been proposed is to use SNPs in clusters (Goddard and Wijsman, 2002). Each cluster is treated as a single multiallelic locus and can be used as an individual locus in

linkage analysis, or in a multipoint analysis with other such loci. Information about local linkage disequilibrium can be used to identify which markers create maximally informative clusters (*see* Article 74, **Finding and using haplotype blocks in candidate gene association studies**, Volume 4). A map has been constructed with clusters of SNPs (Matise *et al*., 2003), with demonstration, as proof of principle, that it can extract as much or more information from real data than do STRPs (Browning *et al*., 2004). It may also be possible to use such an approach with groups of SNPs from other marker panels.

The density of markers is also important. Current SNP panels consist of 5000–11 000 SNPs. Traditional STRP panels consist of ∼400 markers, with a few panels with 800–2000 markers. While, in principle, the denser panels would be expected to provide more information, as well as a somewhat more accurate gene localization, it is not clear that in real data such gains will be realized. In addition, in most cases, it is unlikely that a true linkage signal would be completely missed by the use of a somewhat less dense panel of markers. The advantage of dense SNP panels may be more important for localization, if only because an investigation may be able to proceed directly to fine-scale localization without further genotyping.

7. Quality control

Linkage analysis can be exquisitely sensitive to data error. Methods for detecting error exist (Abecasis *et al*., 2002; Boehnke and Cox, 1997; Epstein *et al*., 2000; Sieberts *et al*., 2002) and take into account the map, allele frequencies, and observed genotype data. These methods are dependent on the same assumptions as are multipoint linkage analysis methods, and violation of these assumptions will also affect the detection of data error. There have been limited attempts to apply the same methods to SNP genotyping. Through simulation, it appears that a relatively high fraction of SNP genotype errors miss detection (Abecasis *et al*., 2002), especially when there are missing data in the pedigrees, as is typical of real data. The lower information for individual SNPs may mean less sensitivity of analyses to genotyping error. However, failure to account for such error will lead to the inefficient use of SNP genotyping. As for linkage analysis methods, extension and improvement of methods to detect or to model genotyping error will be needed to realize the potential of SNPs for linkage analysis.

Additionally, the density of SNP maps relative to STRP maps will draw increasing attention to the variability of human gene maps among individuals and populations. Dense SNP maps include markers that are located within regions that have polymorphic inversions, duplications, and deletions of DNA segments of varying length (*see* Article 55, **Polymorphic inversions, deletions, and duplications in gene mapping**, Volume 1). There is clearly a value in including such markers, as they permit some initial assessment of the possibility that these genomic regions are implicated in disease. This comes at the cost of further extension of methods for genetic analysis to accommodate whole new classes of polymorphisms that challenge the notion of a single, uniform genetic map.

8. Summary

SNPs are a new class of markers. They offer advantages in terms of cost and speed of genotyping. However, to realize the potential of SNPs, analysis must be done with multipoint methods. This has several consequences. The most important are that (1) assumptions that are adequate for sparser maps may not be appropriate for SNP-based analyses, (2) analytic methods and programs implementing such methods will need development and improvement, (3) choice of use of SNP versus STRP-based panels may be affected by factors such as the type of pedigrees and analytic methods to be used, and (4) experience with real data applications is needed to determine the real-life issues with the use of these markers.

1. Introduction

In the field of statistical genetics, specifically in the areas of linkage and association methods (*see* Article 47, **Introduction to gene mapping: linkage at a crossroads**, Volume 1, Article 51, **Choices in gene mapping: populations and family structures**, Volume 1), "the skeleton in the closet" (Sobel *et al*., 2002) is the subject of misclassification errors. Misclassification occurs when an observed measurement is different than its true value. It may be one reason for the lack of replication in gene mapping studies (Page *et al*., 2003) (*see* Article 57, **Genetics of complex diseases: lessons from type 2 diabetes**, Volume 2, Article 64, **Genetics of cognitive disorders**, Volume 2). Therefore, it is critically important for researchers to understand the consequences of error and whether their particular studies are subject to such error.

Misclassification errors may occur in either phenotype (diagnosis) or genotype. Phenotype (or diagnostic) misclassification has been consistently reported in diseases such as Alzheimer's (Lansbury, 2004), Multiple Sclerosis (Poser and Brinar, 2004), Parkinson's (Lansbury, 2004), and Inflammatory Bowel Disease (Silverberg *et al*., 2001) (*see* Article 62, **Inflammation and inflammatory bowel disease**, Volume 2). Genotype errors have been reported as a result of the technology used to determine genotypes, poor sample quality, or simply laboratory error (Bonin *et al*., 2004). Historically, microsatellite loci, which are based on nucleotide repeat sequences, were prone to error rates greater than 5% (Brzustowicz *et al*., 1993) (*see* Article 50, **Gene mapping and the transition from STRPs to SNPs**, Volume 1). New genotype technologies have focused on single nucleotide polymorphisms (SNPs) (single base-pair variation among individuals) because of their high abundance and ease in genotyping. Estimates of SNPs with minor allele frequency greater than 1% are that they occur about once every 290 base pairs, suggesting the existence of 11 million SNPs among the 3.2 billion base pairs in the human genome (Kruglyak and Nickerson, 2001) (*see* Article 53, **Information content in gene mapping**, Volume 1). SNPs are also reported to have lower misclassification rates, with estimates in the range of 0.1%–5% (Hao *et al*., 2004;

Tintle *et al.*, 2005). However, as Bonin *et al.* (2004) point out, genotype error rates will vary depending upon the quality of DNA, expertise of laboratory technicians, and other factors.

1.1. Nondifferential and differential misclassification

A critical distinction regarding the nature of misclassification is that of nondifferential versus differential misclassification error rates. Consider Tables 1a and 1b, which present phenotype and genotype misclassification probabilities, respectively. The conditional probabilities are the error model parameters. Nondifferential misclassification means that the error model parameters have the same value in the different cross-classified groups. For example, nondifferential genotype misclassification means that the error model parameters ϵ_{ij} (Table 1b) have the same values in the Affected and Unaffected groups. Similarly, nondifferential phenotype misclassification means that the error model parameters θ and ϕ (Table 1a) have the sample values in the AA, AB, and BB genotype groups. Mathematically, when:

$$\begin{aligned}&\Pr(\text{observed genotype} = \text{a}|\text{true genotype} = \text{b, true phenotype} = \text{Affected})\\&\quad = \Pr(\text{observed genotype}=\text{a}|\text{true genotype}=\text{b, true phenotype}=\text{Unaffected})\\&\quad = \Pr(\text{observed genotype} = \text{a}|\text{true genotype} = \text{b}),\end{aligned}$$

the genotype misclassification is non-differential.

Differential misclassification occurs when the assumption of nondifferential misclassification is false. The consequences of each type of error are documented below.

1.2. Terminology

We shall use the following terms throughout this work:

(GRR) = genotype relative risk. This term was first defined by Schaid and Sommer (1993). In general, the genotype relative risk is defined as the ratio: $R_i = f_i / f_0$, i = 1, 2. Here, f_i = Pr(*affected* | i copies of disease allele at the trait locus).

Table 1a Conditional probabilities for phenotype misclassification

	Observed Phenotype	
True Phenotype	Affected	Unaffected
Affected	$1 - \theta$	θ
Unaffected	ϕ	$1 - \phi$

In this table we present conditional probabilities Pr (observed phenotype = a | true phenotype = b) where a, b are either Affected or Unaffected. For example, θ = Pr (observed phenotype = Unaffected | true phenotype = Affected).

Table 1b Conditional probabilities for genotype misclassification assuming di-allelic

	Observed genotype		
True Genotype	AA	AB	BB
AA	$1 - \epsilon_{12} - \epsilon_{13}$	ϵ_{12}	ϵ_{13}
AB	ϵ_{21}	$1 - \epsilon_{21} - \epsilon_{23}$	ϵ_{23}
BB	ϵ_{31}	ϵ_{32}	$1 - \epsilon_{31} - \epsilon_{32}$

In this table we present conditional probabilities Pr (observed genotype = a | true genotype = b) where a, b are either AA, AB, or BB. For example, ϵ_{21} = Pr (observed genotype = AA | true genotype = AB).

(MSSN) = Minimum Sample Size Necessary. This term refers to the minimum sample size required to detect association when misclassification errors are present (Gordon *et al*., 2002; Kang *et al*., 2004b; Edwards *et al*., 2005). As is documented below, MSSN almost always increases in the presence of misclassification error.

1.3. Pedigree error

While we do not focus on this issue here, we do note that another source of error for genetic studies is pedigree error, a situation where unrelated individuals are labeled as being part of the same pedigree (*see* Article 78, **Genetic family history, pedigree analysis, and risk assessment**, Volume 2). Methods have been developed both to detect unlikely relationships and to determine the impact of pedigree error on statistical linkage and association statistics [e.g., (Goring and Ott, 1997; Sun *et al*., 2001; Sieberts *et al*., 2002; Sun *et al*., 2002)].

1.4. Missing informativeness

Another issue that we mention in passing regards the consequences of nonrandom missing data for linkage and association analysis. Specifically, we refer to the issue of "informative missingness". Allen *et al*. (2003) define informative missingness for genetic studies with pedigree data as the event that a parent's missing genotype is related to his or her genotype at a locus of interest. They further state, "Informative missingness can occur for several reasons. First, alleles at the locus may, in fact, cause or be proximal to a locus that causes the disease of interest, which may lead to differential missingness. For example, in a study of genetic factors in an aggressive form of cancer, parents carrying the disease-predisposing allele may be more likely to be missing. Second, alleles at the locus may cause or be proximal to a locus causing a different disease that results in parental missingness. In an era when the same candidate genes are tested for involvement in a variety of conditions, this coincidence cannot be ruled out. Alternatively, in genome scans, use of a large number of closely spaced markers increases the chance that a marker is linked to some locus that may cause parental missingness by association

with a disease other than the one under study. Finally, if there is population substructure and if the propensity to be missing is correlated with allele frequency in the subpopulations, then the genotype frequencies in the intact trios will not be representative of those among the missing parents." These authors present statistical methods to address informative missingness in case-parent designs (Allen *et al*., 2003). Other authors have also looked at this issue with regard to genetic association (Chen, 2004).

2. Error detection

Phenotype misclassification may be determined by the use of a "gold-standard" diagnosis (e.g., autopsy-proven diagnosis in diseases such as Alzheimer's, Parkinson's, and Multiple Sclerosis (Mayeux *et al*., 1998; Poser and Brinar, 2001; Lansbury, 2004)), by rigorous review of clinical records of all the patients involved in a study (Silverberg *et al*., 2001), or by diagnosis performed by two independent investigators. Autopsy-proven diagnosis will usually not be available on all the patients in a study unless that is part of the study design. Since rigorous review of clinical records is time-consuming and expensive, it may not be feasible to conduct it for all patients. If clinical measurement instruments are subject to higher error rates (say >10%), then even independent diagnoses still have a greater than 1% probability of both being incorrect.

Regarding genotype misclassification, methods of error detection for pedigree data have focused on detecting single-locus Mendelian inconsistencies (O'Connell and Weeks, 1998) or determination of unlikely genotypes through multipoint and other methods (Ehm *et al*., 1996; Douglas *et al*., 2000). Recent research suggests that error detection through Mendelian inconsistency has low and variable power (<70%), especially for SNP genotypes with larger minor allele frequencies (Gordon *et al*., 1999a; Gordon *et al*., 2000; Douglas *et al*., 2002; Geller and Ziegler, 2002). Furthermore, even if a pedigree demonstrates Mendelian inconsistency, unless one uses a gold-standard genotyping technology (which usually is expensive and is not performed on all the subjects) or makes restrictive assumptions about the nature of genotype errors (e.g., (Miller *et al*., 2002)), one cannot determine which genotype is true and which is incorrect. Simulation studies also indicate that a nonsignificant proportion of genotype errors are not detected by multipoint methods (Badzioch *et al*., 2003; Zou *et al*., 2003; Mukhopadhyay *et al*., 2004).

In population-based studies such as case/control genetic association analysis (*see* Article 1, **Population genomics: patterns of genetic variation within populations**, Volume 1, Article 51, **Choices in gene mapping: populations and family structures**, Volume 1), methods for genotype error detection focus on either repeated sampling (Miller *et al*., 2002; Gordon *et al*., 2004b) or tests for deviation from the Hardy-Weinberg Equilibrium in control subjects (Hosking *et al*., 2004; Ott, 2004). Recent research suggests that tests for deviation from the Hardy-Weinberg Equilibrium in control subjects may require prohibitively large sample sizes (Leal, 2005).

3. Consequences of error

3.1. Association studies

3.1.1. Nondifferential misclassification

For nondifferential misclassification errors, the main consequence of errors is a loss in power to detect association or, equivalently, an increase in sample size necessary to maintain constant power for any given significance level. For phenotype misclassification using 2×2 contingency tables (e.g., case/control and exposure/nonexposure), Bross (1954) showed that there is no change in the level of significance for the chi-square test of independence, that parameter estimates are biased, and that there is a loss in power to detect association. In the field of epidemiology, as reviewed by Thomas *et al*. (1993), the issue of phenotype misclassification has been widely studied.

Two statistical applications for genetic association data are the linear trend statistic (Cochran, 1954; Armitage, 1955) and the chi-square test of independence on $2 \times c$ contingency tables, where c is the number of observed genotypes. Regarding the linear trend test, Zheng and Tian (2005) quantified the sample size requirements to detect association in the presence of phenotype (or diagnostic) misclassification as a function of the genetic model parameters including GRRs (Schaid and Sommer, 1993), disease allele frequency, and disease prevalence K. Edwards *et al*. (2005) considered this issue for the chi-square test of independence on contingency tables. Specifically, they computed sample size requirements in the presence of phenotype misclassification and used a linear Taylor series approximation to determine the relative costs of misclassifying a true affected (respectively, unaffected) as an observed unaffected (respectively, affected). A key finding was that the MSSN coefficient of misclassifying a true affected as an observed unaffected was proportional to:

$$K/(1 - K). \tag{1}$$

Similarly, the MSSN coefficient of misclassifying a true unaffected as an observed affected was proportional to:

$$(1 - K)/K. \tag{2}$$

From formula (2), as the prevalence K in the population being studied approaches 0 (*see* Article 59, **The common disease common variant concept**, Volume 2, Article 60, **Population selection in complex disease gene mapping**, Volume 2, Article 68, **Approach to common chronic disorders of adulthood**, Volume 2), the MSSN coefficient becomes indefinitely large. That is, the sample size requirements to maintain constant power become prohibitively large. Figure 1 illustrates the rapid increase in MSSN for nonzero error rate ϕ = Pr(observed affected | true unaffected) when the prevalence decreases. The sample size requirements go from 100 ($\log_{10} = 2.0$) for $K = 0.069$, $\phi = 0.001$ to 388

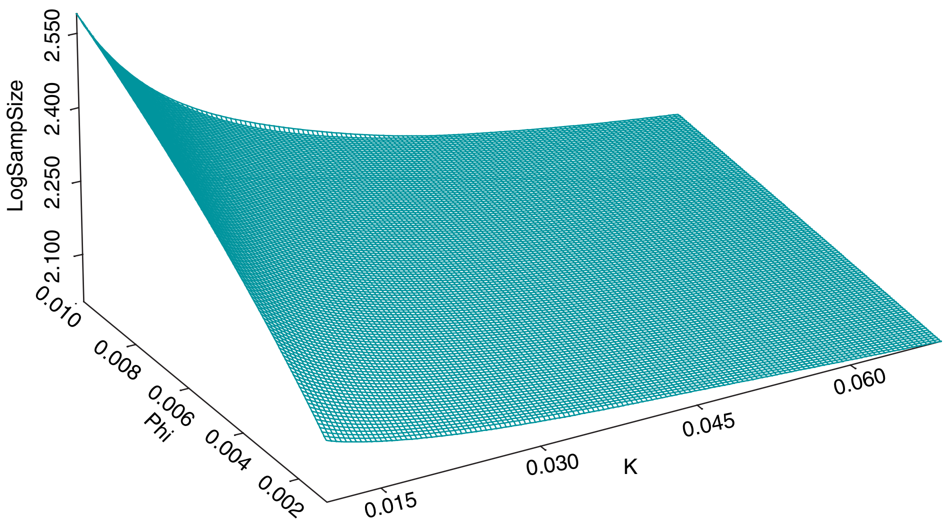

Figure 1 Sample size requirements (log transformed) as function of disease prevalence K and misclassification error rate θ. Total sample size (cases and controls; $\log_{10}$-transformed) is computed as implemented in the PAWE-3D webtool (**http://linkage.rockefeller.edu/pawe3 d/**) using the following genetic model parameter settings: genotype relative risks (GRR) $R_1 = 3$, $R_2 = 10$, Disease allele frequency = 0.25, SNP marker allele frequency = 0.25, r^2 = 1.0, power = 0.95, significance level = 0.05, chi-square test of independence on 2 degrees of freedom, Theta = Pr (observed unaffected | true affected) = 0.01, Phi = Pr (observed affected | true unaffected), and prevalence K . Sample sizes are plotted for Phi in the range [0.001, 0.01] and K in the range [0.01, 0.07]

($\log_{10} = 2.59$) for $K = 0.01$, ϕ=0.01. In general, power and sample size calculations for case/control studies of genetic association may be performed using the *P*ower for *A*ssociation *W*ith *E*rrors webtool (PAWE-3D) (Gordon *et al*., 2005).

Consequences of genotype error are that there is no change in the level of significance for the chi-square test of independence, that parameter estimates are biased, and that there is a loss in power to detect association. However, power loss does *not* depend upon prevalence, as with phenotype error. For the chi-square test of independence, power loss or MSSN for fixed power has been quantified (Mote and Anderson, 1965) and MSSN cost coefficients have been calculated for either a genetic model-based or model-free setting (Kang *et al*., 2004a; Kang *et al*., 2004b). This research indicates that the most costly error for a di-allelic locus such as SNP is misclassification of the more common homozygote as the less common homozygote, with unbounded MSSN coefficient as the minor allele frequency approaches 0. Another genotype error with unbounded MSSN coefficient is misclassification of the more common homozygote as the heterozygote. Kang *et al*. (2004a) demonstrated that for certain recessive genetic models, the MSSN coefficient for misclassification of the heterozygote as the less common homozygote was unbounded as the SNP minor allele frequency and the disease allele frequency approach 0. That is, as the minor allele frequency of SNP locus approaches 0, the sample size requirements to maintain constant power for even a 1% rate of these types of error approaches infinity. Therefore,

researchers should be particularly careful in calling genotypes when SNP minor allele frequencies are small (*see* Article 50, **Gene mapping and the transition from STRPs to SNPs**, Volume 1, Article 53, **Information content in gene mapping**, Volume 1).

Finally, genotype error can lead to erroneous inferences when measures of linkage disequilibrium between two samples are compared (Akey *et al*., 2001), to power loss for association when DNA pooling techniques are applied (Zou and Zhao, 2004), and to erroneous inference for population genetics studies based on individual identification (Bonin *et al*., 2004).

3.1.2. Differential misclassification

Differential misclassification is the most damaging type of misclassification from a statistical standpoint. If differential misclassification occurs, one does not know the null distribution of the test statistic unless one knows the error model parameters and can perform simulations under the null hypothesis of no association. So, for example, Bross's finding (1954) that the level of significance for the chi-square test of independence does not change under misclassification may no longer be true when differential misclassification occurs. In a recent publication, Clayton *et al*. (2005) documented a substantial inflation in type I error for a case-control genetic association study of type I diabetes due to differential genotyping misclassification. That is, individual SNP genotype error rates were different in the case and control populations.

How can one avoid such misclassification? One answer is randomization. For example, to avoid differential genotype misclassification, one should not perform genotyping of all cases at one-time and all controls at another time, but rather randomly assign genotyping platform runs independent of affection status.

3.2. Linkage studies

In this section we focus on nondifferential errors, as we are unaware of research that has considered differential misclassification in linkage methods. Phenotype misclassification has been consistently studied in linkage analysis over the past few decades (e.g., (Ott, 1977; Martinez *et al*., 1989; Burd *et al*., 2001; Silverberg *et al*., 2001)). Major findings are that there is loss in power to detect linkage and that estimates of the recombination fraction between disease locus and marker locus are too large, on average. Thus, the existence of phenotype misclassification can make gene mapping more difficult either because initial linkage analyses do not show significant evidence for linkage to disease loci and/or because the position of a disease locus may be several centiMorgans away from its estimated position (Martinez *et al*., 1989).

For genotype errors, a number of authors have looked at the effects in linkage studies. Results are summarized by Sobel *et al*. (2002). Major findings are that errors lead to inflation in genetic map distances (Buetow, 1991; Shields *et al*., 1991; Goldstein *et al*., 1997; Matise *et al*., 2003); an increase in type I error (false positive) rates (Gordon *et al*., 2001; Becker and

Knapp, 2003; Mitchell *et al*., 2003; Knapp and Becker, 2004; Seaman and Holmans, 2005); a decrease in power for statistical methods designed for gene localization (Gordon *et al*., 1999b; Abecasis *et al*., 2001; Gordon and Finch, 2005); biased estimates of parameters such as the recombination fraction among loci (Terwilliger *et al*., 1990); and biased estimates of population frequency parameters such as haplotype frequencies (Kirk and Cardon, 2002; Becker and Knapp, 2003).

3.2.1. Genotype errors in TDT analysis

Of particular importance is the consideration of genotype errors in transmission/disequilibrium test (TDT) linkage analysis (Spielman *et al*., 1993; Spielman and Ewens, 1996). A number of software programs that perform TDT analysis only do so for pedigrees showing Mendelian consistency. Thus, for researchers to run the software, they must "clean" the pedigrees. Cleaning is often done by removing (or "zeroing out") genotypes for individuals causing Mendelian inconsistency (O'Connell and Weeks, 1998; Mukhopadhyay *et al*., 1999). Still other software programs simply ignore those pedigrees that show Mendelian inconsistency. Unfortunately, especially for SNPs, many genotype errors will not result in Mendelian inconsistency (Gordon *et al*., 1999a; Gordon *et al*., 2000; Douglas *et al*., 2002; Geller and Ziegler, 2002). The result is that many pedigrees with genotype errors remain in the data set and are incorrectly considered in the calculation of the TDT statistic. An example is provided in Figures 2a and 2b. In figure 2a, we see that the true genotype status of all individuals is homozygous for the A allele. Since the TDT only considers those pedigrees in which at least one parent is heterozygous (Spielman *et al*., 1993), this pedigree should not be included in the calculation of the TDT statistic, because both parents are homozygous at the marker allele. Consider now the same pedigree after a genotype error is introduced, resulting in the father's marker genotype being recorded as the heterozygote AB. This error will not be detected by checking for Mendelian inconsistency. As a result, this pedigree will incorrectly be included in the calculation of the TDT statistic. The effect of such inclusions is a possibly substantial increase in the false-positive rate to detect linkage (Gordon *et al*., 2001; Mitchell *et al*., 2003). For example, Gordon *et al*. (2001) documented by simulation that, for 500 trio pedigrees, assuming a 5% misclassification of the B allele as the A allele, the false-positive rate at the 1% significance level was 11.8%, an eleven-fold increase. Furthermore, the inflation in false-positive rate increases as the sample size increases, because the absolute number of pedigrees with undetected genotype errors increases (even though the proportion of pedigrees with errors remains constant for a fixed genotype error rate). This issue of genotype error is likely to become more important rather than less for the foreseeable future, as many genetic analysis designs call for larger sample sizes (>500 trio pedigrees) with more than 100,000 genotyped SNPs across the genome (*see* Article 52, **Algorithmic improvements in gene mapping**, Volume 1, Article 51, **Choices in gene mapping: populations and family structures**, Volume 1).

Figure 2 Example of pedigree that is incorrectly included in TDT analysis. These figures show genotypes for di-allelic locus with alleles A and B in a pedigree (father [open square], mother [open circle], affected daughter [dark circle]) before (a) and after (b) a genotype error is introduced into the pedigree. In this example, the father's genotype is changed from AA to AB

4. Statistical solutions to address challenges arising from phenotype and genotype errors

As noted above, the main challenges arising from nondifferential phenotype and genotype error rates are a loss in power for gene mapping studies, biased estimates of the position of a disease locus, biased estimates of population frequency parameters, and an increase in false-positive rates for TDT. A traditional approach (for nondifferential misclassification only) to address the issue of power loss is to increase sample size (Wong *et al*., 2003). However, methodological research has documented that the sample size requirements may be prohibitively high, especially if the prevalence of the disease is small, the effect size of the susceptibility gene is modest, and/or the misclassification rates are large (e.g., greater than 5%) (Martinez *et al*., 1989; Silverberg *et al*., 2001; Edwards *et al*., 2005; Zheng and Tian, 2005).

4.1. Incorporation of errors into design and analysis

We and others (Badzioch *et al*., 2003; Mukhopadhyay *et al*., 2004) recommend incorporation of misclassification error into the design and analysis of genetic linkage and association data. At the design stage, one can compute more realistic power and sample size values for genetic association studies by incorporation of nonzero phenotype and/or genotype misclassification error rates (Gordon *et al*., 2002, 2005). Given that low disease prevalence is a critical factor in power loss for phenotype misclassification (see equation (2)), a more robust study design is one in which the phenotype of interest is closer to 50% in the population being studied. For example, in pharmacogenetic association studies (*see* Article 73, **The clinical and economic implications of pharmacogenomics**, Volume 2), one can use as the phenotype responders or nonresponders to particular medications and/or treatments, which may have prevalences closer to 0.5. With genotype misclassification, one can perform sample size calculations assuming a larger rather than a smaller power (say, 99% vs. 80%) to protect against substantial power loss. A sample size chosen to have 99% power without errors for a trait locus that displays a dominant mode of inheritance will still have 95.5% power after a 5% genotyping error rate, whereas a sample size chosen to have 80% power without errors for the same mode of

Table 2 Software programs referenced in this work that consider phenotype and/or genotype misclassification error

Program	Description	Reference	URL
LRTae	Perform case/control genetic association analysis allowing for phenotype/genotype error by use of double-sampling	(Gordon *et al*., 2004b)	**ftp://linkage.rockefeller.edu/software/lrtae/**
Mendel/Simwalk	Check for unlikely genotypes in pedigree data using multipoint methods and assuming specific genotype error model	(Sobel and Lange, 1996; Sobel *et al*., 2002)	**http://www.genetics.ucla.edu/software/**
Merlin	Checks for genotype errors in pedigree data through Mendelian inconsistencies and multipoint methods	(Abecasis *et al*., 2002)	**http://www.sph.umich.edu/csg/abecasis/Merlin**
PAWE/PAWE-PH/PAWE-3D	Perform power/sample size calculations for case/control genetic association incorporating phenotype and genotype errors	(Gordon *et al*., 2002; Edwards *et al*., 2005; Gordon *et al*., 2005; Zheng and Tian, 2005)	**http://linkage.rockefeller.edu/pawe/**
PedCheck	Check for Mendelian inconsistencies (genotype errors) in pedigree data	(O'Connell and Weeks, 1998)	**http://watson.hgen.pitt.edu/register**
PseudoMarker	Perform multipoint linkage and association analysis on pedigree data allowing for genetic model misspecification and genotype errors	(Goring and Terwilliger, 2000a; Goring and Terwilliger, 2000b; Goring and Terwilliger 2000c; Goring and Terwilliger 2000 d)	**http://www.helsinki.fi/~tsjuntun/pseudomarker/**
TDTae	Perform TDT linkage analysis allowing for single-locus genotype errors	(Gordon *et al*., 2001; Gordon *et al*., 2004a)	**ftp://linkage.rockefeller.edu/software/tdtae2/**

In this table, we present a list of some currently available software methods to either detect phenotype and genotype errors or to integrate such errors into linkage and association analyses. Another program that is not listed in the table is one developed by Hao *et al*. (2004). Their method estimates genotype error rates from pedigree data. A software program is available by contacting the author (khao@hsph.harvard.edu).

inheritance will only have 65.4% power with the same 5% genotyping error rate (Gordon and Finch, 2005).

Statistical methods have also been developed that allow for genotyping error when estimating haplotype frequencies in either unrelated individuals or nuclear families (Zou and Zhao, 2003).

If a gold-standard phenotype or genotype measurement is available for a subset of individuals, then one can incorporate such information in a likelihood ratio test of association to increase power for gene mapping and also to determine unbiased estimates of genotype frequencies (Tenenbein, 1970; Tenenbein, 1972; Gordon *et al*., 2004b). Freely available software has been developed to compute the test statistic for multilocus genotype data on cases and controls (see Software). If one assumes a single-parameter error model (i.e., all $\epsilon_{ij} = \epsilon$ in Table 2), then one can genotype a subset of individuals for a given SNP and determine an estimate of the genotype error. This estimate can be used in a test of association to determine unbiased estimates of genetic model parameters such as GRRs (Rice and Holmans, 2003).

For linkage analysis with pedigree data, there are several methods to deal with phenotype misclassification that involve some form of averaging over genetic model parameters as a means of treating the bias in the parameters due to phenotype misclassification (Vieland, 1998; Goring and Terwilliger, 2000d). Software using a likelihood approach is available (Goring and Terwilliger, 2000d).

For TDT, statistical methods have been developed that incorporate pedigrees with genotype error into the analysis without inflation of false-positive rates (Bernardinelli *et al*., 2004; Gordon *et al*., 2004a; Morris and Kaplan, 2004). These methods have been successfully applied to gene mapping studies of diseases like psoriasis (Helms *et al*., 2003; Helms *et al*., 2005) and software is available.

5. Software

In table 2, we present a list of available software programs that consider the issue of phenotype and/or genotype misclassification error. These programs may be used at the design stage (power and sample size calculations), the processing stage (detecting genotype errors in pedigree genetic data), or the analysis stage (incorporating phenotype and genotype errors into the statistical analysis of genetic data).

Short Specialist Review

Choices in gene mapping: populations and family structures

Toni I. Pollin and Jeffrey R. O'Connell
University of Maryland School of Medicine, Baltimore, MD, USA

1. Introduction

The goal of gene mapping is to find genes whose variation causes or contributes to a phenotype of interest. Thus, choice of population for gene mapping at its most fundamental level depends on the role of the genes in the underlying biochemical pathway(s) responsible for the phenotype. In choosing a population to study, we choose between specific ethnic groups, between populations with varying degrees of genetic isolation, and between sampling schemes (i.e., nuclear families, extended families, sibling-parent trios, sibling pairs, unrelated sets of affected cases and unaffected controls). The mathematical models used to describe genotype–phenotype relationships of susceptibility genes in complex diseases depend on factors such as the population history of the disease, disease prevalence, allele and genotype penetrance, phenocopy rate, gene-by-gene and gene-by-environment interaction, and allelic spectrum of the disease.

While these models may provide guidelines, practical issues such as the phenotyping and genotyping costs and recruitment feasibility often have a greater impact on the populations we choose to study. For example, regardless of the power of discordant sibling pairs to map quantitative traits, ascertaining sufficient numbers may just not be feasible if such pairs are very rare in the population.

Given that our models certainly do not capture the full complexity of the biology and that inferences made from the models depend on the values of the input parameters, it is not surprising that there is debate in the literature regarding how and in whom it is best to map genes for complex diseases. One central issue is whether the allelic architecture (number and diversity of disease-causing alleles) of susceptibility genes for complex diseases is the same as or similar to that for Mendelian diseases. The common disease/common variant (CDCV) hypothesis (Lander, 1996; Risch and Merikangas, 1996) states that many common diseases are caused by alleles that have been driven to high frequency under neutral selection pressure, as the diseases have late onset, or even positive selection pressure in past environments as considered by the thrifty gene hypothesis (Neel, 1961). Examples of genes with common variants associated with complex diseases include the *APOE* gene in Alzheimer's disease (Corder *et al*., 1993) and PPARγ in Type 2 diabetes (Yen *et al*., 1997; Altshuler *et al*., 2000). Under the CDCV hypothesis, linkage

analysis is expected to have limited power compared to testing for association between allelic variants and disease in population samples.

The prospect of genome-wide association mapping is fundamentally tied to the rapid advances in genotyping technology of single-nucleotide polymorphisms (SNPs). The number of SNPs available for high-throughput mapping has increased exponentially in the last several years. One goal of the HapMap Project is to provide a scaffold of SNPs based on the linkage disequilibrium (LD) patterns in the genome that adequately powers association mapping given that the risk allele may not be tested directly. Since required sample sizes depend on the effect size of the risk allele and amount of LD between the risk allele and the tested SNP, many companies, such as deCODE genetics, and governments, such as those of the United Kingdom and Japan, are turning to very large-scale population-based biobanks that contain DNA samples from hundreds of thousands of individuals (Wright *et al*., 2002; Triendl, 2003). The practical and ethical implications of these biobanks, such as the feasibility of obtaining informed consent from individuals for DNA banking for future, often unknown, research purposes, are subjects currently under discussion (MacWilliams, 2003).

2. Advantages of genetic isolates

Genetic isolates have been used quite successfully to map many Mendelian diseases, particularly, rare recessive disorders that become prevalent due to inbreeding, such as Ellis–van Creveld syndrome in the Amish (Ruiz-Perez *et al*., 2000) and Bardet–Biedl syndrome in the Bedouins (Nishimura *et al*., 2001). Although it is still unknown whether genetic isolates will prove to be equally valuable for mapping complex diseases, there have been a number of recent articles in the literature emphasizing the potential advantages of these populations (Ober and Cox, 1998; Wright *et al*., 1999; Peltonen *et al*., 2000; Shifman and Darvasi, 2001; Heutink and Oostra, 2002).

Some clear advantages are genetic homogeneity resulting from a small number of founder chromosomes and environmental homogeneity arising from common cultural or religious practices or geographical isolation. Genetic homogeneity reduces the number of susceptibility alleles segregating in the population, and environmental homogeneity reduces the proportion of the total variance in a trait attributable to nongenetic factors. Longitudinal studies, which can provide a clearer understanding of phenotypes that are influenced by developmental processes and gene-by-environment interactions, may be easier to perform in isolates that are also geographically localized. This geographical localization combined with other features such as cultural homogeneity has in some cases afforded researchers the opportunity to develop mutually beneficial, culturally sensitive, collaborative relationships with genetic isolate communities; perhaps the most notable example is the involvement in genetic research of the Old Order Amish over the past 40 years (McKusick *et al*., 1964; Francomano *et al*., 2003). Under the CDCV hypothesis, susceptibility alleles that are present in genetic isolates should be relevant to the outbred populations from which the founders came, as there has not been sufficient time for these alleles to be replaced by new variants. This hypothesis is supported

by recent empiric data showing that estimated frequencies of SNPs in candidate genes for cardiovascular risk were indeed similar between the Hutterites and CEPH families (Newman *et al*., 2004). Linkage disequilibrium generally extends over greater distances in younger genetic isolates, therefore requiring fewer SNPs for linkage disequilibrium (LD) mapping.

However, we are of the opinion that the true power of genetic isolates for studying complex disease has yet to be tapped, as their power lies not in the genotyping technologies of the HapMap Project to exploit LD mapping but rather in the sequencing technologies of the Personal Genome Project that promise to provide the $1000 sequence in 24 hours. Many of these revolutionary technologies are based on genotyping single molecules of DNA (Kwok and Xiao, 2004), and therefore will provide molecular haplotypes. Because haplotype phase can be at least partially determined within pedigrees when using standard diploid genotyping, interest in the molecular haplotype has been focused primarily on LD mapping in case-control studies. However, the molecular haplotype perhaps has its greatest power in eliminating the computational barriers faced in linkage and association analysis within genetic isolates.

The power of the molecular haplotype has actually already been used in genetic isolates such as the Bedouins, Finnish, and Old Order Amish for mapping rare recessive diseases that arise from inbreeding in the form of homozygosity mapping. Homozygosity mapping is based on the principle that an affected individual homozygous for a rare deleterious allele will be homozygous at nearby flanking polymorphic markers if the disease alleles were inherited identical by descent from a common ancestor (Lander and Botstein, 1987). Determining regions of homozygosity is equivalent to determining shared ancestral molecular haplotypes. The regions can be inferred with dense genotyping of polymorphic markers to detect sequences of homozygous genotypes whose length is greater than that expected by chance given the allele frequencies, with the heterozygous genotypes that interrupt the sequence defining the boundaries.

For complex diseases in genetic isolates, the principle is the same; that is, affected individuals carrying an ancestral risk allele will be enriched for a portion of the ancestral haplotype containing the risk allele, and the enrichment of the risk allele results from the multilineal paths of descent created by inbreeding. However, for complex diseases, the risk haplotype may be neither necessary nor sufficient to develop disease. Given that two haploid chromosomes differ by, on average, one nucleotide per kilobase, single-molecule genotyping will allow us to directly infer regions of identity by descent (IBD) between any two chromosomes on the basis of the length of sequence similarity.

This technology will eliminate the major computational obstacle of computing mulitipoint IBD sharing probabilities in pedigrees from young genetic isolates, such as the Old Order Amish, with 10–14 generations, thousands of individuals, and often hundreds of inbreeding loops (O'Connell, 2003). Direct IBD between two haploids is inferred from matching sequence rather than from a likelihood calculation on a complex ancestral pedigree structure, often comprising 5–7 generations with no genotype information. The genealogy is only required for the unconditional IBD sharing probabilities, which are straightforward to compute. Haploid genotyping will potentially allow such pedigrees to be analyzed in their

entirety, thereby incorporating a much broader and deeper recombination history to reduce the length of shared ancestral haplotypes that contain susceptibility genes to complex disease.

Certainly, no single population or gene mapping approach will provide all the answers to our questions about the genetics of complex diseases, but the prospect of single-molecule technologies providing large-scale affordable sequencing on the haploid background will unlock the true richness of genetic isolates in the study of complex diseases. Thus, we would advocate establishing biobanks specific to genetic isolates, a resource likely enhanced by the close-knit nature of these populations and our consequent ability to work closely with them as collaborators, to complement the growing number of outbred population-based biobanks.

Short Specialist Review

Algorithmic improvements in gene mapping

Gonçalo R. Abecasis and Yu Zhao
University of Michigan, Ann Arbor, MI, USA

1. Introduction

The analysis of human gene mapping data has generated many challenging computational problems. The challenges arise because in most gene-mapping studies the DNA sequence of each individual is only measured imperfectly. For some individuals, these measurements are the result of genotyping assays at specific loci or chromosomal regions. For other individuals, there might be even greater uncertainty: their DNA sequence might only be measured indirectly through information obtained on the genotypes of their relatives. In either situation, there can be a very large number of DNA sequences compatible with observed data, and identifying the most likely DNA sequence configuration(s) might require many individuals to be considered jointly.

2. Analysis of human pedigrees

To survey algorithmic challenges in gene mapping, we will focus on the analysis of pedigree data. These data are often used in linkage studies of discrete or quantitative traits, in the construction of genetic linkage maps (*see* Article 54, **Sex-specific maps and consequences for linkage mapping**, Volume 1), in quality assessments for genotyping data, or to identify individual haplotypes. Maximum likelihood can solve these and other problems related to the analysis of pedigree data, and many algorithms have been developed to calculate likelihoods for human pedigrees. Briefly, the likelihood of interest can be written as:

$$L(\text{data}) = \sum_{G_l} \ldots \sum_{G_n} \prod_i P(X_i|G_i) \prod_{\text{founder}} P(G_{\text{founder}}) \prod_{\{o,f,m\}} P(G_o|G_f, G_m) \quad (1)$$

This likelihood involves a nested summation over the set of possible haplo-genotypes, G_i, for each individual. The likelihood of each possible configuration is a product with factors denoting (1) the probability of observed phenotypes conditional on each individual haplo-genotype, $P(X_i|G_i)$; (2) the probability of

founder haplo-genotypes, $P(G_{\text{founder}})$; and (3) the probability of offspring haplo-genotypes conditional on parental haplo-genotypes, $P(G_o|G_f, G_m)$, calculated for all parent-offspring triples.

Direct evaluation of this nested sum is only possible in the simplest of cases, involving a very small number of loci and individuals. The number of summation terms to be evaluated increases exponentially with both the number of individuals in the pedigree (which add extra levels to the nested sum) and the number of markers being considered (which increase the number of possible haplo-genotypes for each individual).

In early gene-mapping studies, investigators painstakingly evaluated likelihoods for each pedigree examined, using careful algebra to factor the calculation and identify repeated terms. Gene mapping was a new field, laboratory methods were rudimentary allowing the use of only small amounts of data, and this laborious approach was adequate.

3. The Elston–Stewart and related algorithms

Elston and Stewart (1971) developed the first general algorithm for rapid pedigree likelihood calculation. They showed that the likelihood could be updated gradually, one nuclear family at a time. Each update required iterating over possible genotypes for individuals in the nuclear family, resulting in a relatively small nested sum. Their strategy proved highly effective, and their algorithm is still the method of choice for the analysis of large, noninbred pedigrees. Their method was later implemented in LIPED, the first widely available automated software for pedigree likelihood calculation (Ott, 1976), which played a crucial role in enabling the gene-mapping revolution.

Many improvements to the basic algorithm have been proposed. For example, Cannings *et al*. (1978) showed how the method could – in theory – be applied to complex pedigrees, even with inbreeding. Lange and Boehnke (1983) showed that the likelihood could be updated one individual, rather than one nuclear family at a time, and that different sequences of updates could produce dramatically different computing time and memory requirements. With these improved formulations, the complexity of calculating likelihoods for most noninbred pedigrees increases linearly with the number of individuals in a family, and likelihoods can be calculated for very large pedigrees, including hundreds of individuals. Another important enhancement was the development of algorithms for identifying sets of haplo-genotypes for each individual compatible with the observed genotypes for each family (Lange and Goradia, 1987).

In parallel to these algorithmic improvements, more sophisticated computer implementations of the Elston–Stewart algorithm were developed. The LINKAGE computer package (Lathrop *et al*., 1984; Lathrop *et al*., 1985) enabled geneticists to analyze multiple marker loci jointly. Together with the discovery of highly polymorphic VNTR and microsatellite markers, LINKAGE enabled the localization of genes for many Mendelian disorders through multilocus linkage analysis in relatively large pedigrees.

In the 1990s, further enhancements to the Elston–Stewart algorithm were discovered. Cottingham *et al*. (1993) used improved software engineering techniques, such as caching and replacement of floating point with integer operations, to speed up LINKAGE by about one order of magnitude. O'Connell and Weeks (1995) showed that combining alleles that do not appear in an individual's descendants in a single meta-allele could dramatically reduce the number of distinct haplo-genotypes and further speed up calculation.

Despite these enhancements, the complexity of likelihood calculations using the Elston–Stewart algorithm grows exponentially with the number of marker loci considered. State-of-the-art implementations of the Elston–Stewart algorithm in the VITESSE (O'Connell and Weeks, 1995) and FASTLINK (Cottingham *et al*., 1993) computer packages cannot handle more than 5–10 marker loci at a time. The ability of geneticists to rapidly collect data for hundreds of microsatellite markers and the interest in complex disease gene mapping using large collections of small pedigrees shifted the focus to a different collection of algorithms.

4. The Lander–Green and related algorithms

Lander and Green (1987) proposed a very different strategy for pedigree likelihood calculations. Their approach is based on the use of inheritance vectors, which summarize inheritance at specific genomic location. They showed that the probability of observed genotypic or phenotypic data can be calculated for any particular inheritance vector and that, in the absence of genetic interference, inheritance vectors form a Markov Chain along the chromosome. Using a Hidden Markov Model, they proposed an algorithm for the calculation of pedigree likelihoods whose complexity increased only linearly with the number of markers. The algorithm is suitable for very large numbers of markers, but limited to relatively small pedigrees because the number of possible inheritance vectors increases exponentially with pedigree size.

As with the Elston–Stewart algorithm, many enhancements were later discovered, and progressively more powerful computer implementations contributed to the success of countless gene-mapping studies. One important enhancement resulted from the observation that there are many redundancies within inheritance vector space so that inheritance vectors can be grouped to speed up calculation. Over the years, progressively more sophisticated strategies were developed for identifying these redundancies, first focusing on symmetries resulting from the transmission of alleles from single founders (Kruglyak *et al*., 1996), then founder couples (Gudbjartsson *et al*., 2000), and later from other individuals in the pedigree (Markianos *et al*., 2001; Abecasis *et al*., 2002). Another important series of improvements focused on the manipulation of transition matrices, used for the calculation of conditional inheritance vector distributions at neighboring locations, a key step in the Markov Chain. Two distinct approaches have proved very successful at speeding up this step of the calculation: either a divide-and-conquer algorithm (Idury and Elston, 1997) or Fast Fourier Transform (Kruglyak and Lander, 1998) can reduce the computational cost of generating these conditional distributions by several orders of magnitude.

Popular implementations of the Lander–Green algorithm include the computer packages GENEHUNTER (Kruglyak *et al*., 1996; Markianos *et al*., 2001), ALLEGRO (Gudbjartsson *et al*., 2000), and MERLIN (Abecasis *et al*., 2002). All these packages can handle very large numbers of markers and allow the estimation of individual haplotypes or the analysis of quantitative and discrete traits, providing parametric and nonparametric linkage tests. They also provide more specialized algorithms including, for example, algorithms that estimate information content along the genome. Relative information content can highlight areas where genotyping additional markers would provide the greatest information gain (*see* Article 53, **Information content in gene mapping**, Volume 1). In addition to these standard features, the newer packages can generate simulated datasets (commonly used for calculating empirical significance levels), carry out more accurate linkage tests (Kong and Cox, 1997; Sham *et al*., 2002), and even identify likely genotyping errors (Abecasis *et al*., 2004).

Although current implementations of the Lander–Green algorithm can comfortably handle hundreds and even thousands of genetic markers, advances in laboratory technology are already highlighting a need for even more powerful methods. The shift to SNP (single-nucleotide polymorphism) markers and very large scale genotyping has generated datasets with hundreds of thousands of markers measured per individual, with substantial amounts of linkage disequilibrium between neighboring markers (*see* Article 50, **Gene mapping and the transition from STRPs to SNPs**, Volume 1). It is likely that further enhancements to gene-mapping algorithms will be forthcoming to allow the analysis of these new datasets.

5. Markov-chain Monte-Carlo algorithms

While the Elston–Stewart and related algorithms can handle a small number of markers in very large noninbred pedigrees and the Lander–Green and related algorithms can handle very large numbers of markers in small pedigrees, neither approach can handle a large number of markers in a large pedigree. Very large pedigrees arise in many interesting settings, most often in the study of isolated populations (*see* Article 51, **Choices in gene mapping: populations and family structures**, Volume 1). It is often desirable to analyze multiple genetic markers in these pedigrees to clarify inheritance patterns when genotype data are not available for individuals in the early generations. The analysis of these most challenging datasets has motivated the development of Monte-Carlo-based methods, which try to identify the most important terms in the pedigree likelihood but avoid summing over all possible terms.

A variety of Monte-Carlo approaches have been employed successfully in linkage analysis, including Simulated Annealing (Sobel and Lange, 1996, implemented in the SIMWALK2 computer program), the Gibbs sampler (Heath, 1997, implemented in the LOKI computer program), and Sequential Imputation (Irwin *et al*., 1994). In addition to the ability to handle very large datasets, these software packages often provide capabilities not currently available in packages based on the Elston–Stewart or Lander–Green algorithms. For example, LOKI (Heath, 1997) can model the contributions of multiple susceptibility loci simultaneously and

SIMWALK2 (Sobel and Lange, 1996; Sobel *et al*., 2002) can model genotyping error explicitly.

6. Outlook for the future

While this is an incomplete account of all the algorithms developed for the linkage analysis of human pedigrees, we have attempted to emphasize those algorithms and developments that entered widespread use through the availability of easy-to-use computer programs. We have certainly missed some packages and ideas that deserve credit, as well as some research paths and strategies that were tried along the way but never become popular in practice. Currently, one promising avenue appears to be the use of Bayesian Networks (Jensen, 1996). These allow complex likelihoods to be evaluated gradually, and provide for a more flexible updating scheme than the Lander–Green or Elston–Stewart algorithms, which conduct updates considering either all individuals (for one locus) or all loci (for one or more individuals) at a time.

The past 20–30 years have produced many algorithmic advances in the analysis of human pedigrees, and these have enabled geneticists to extract the full benefits of new laboratory methods that allow the collection of increasing amounts of genetic information on increasing samples of individuals. Whereas initial methods focused on the analysis of single genetic markers and simple Mendelian traits, more modern methods can analyze very large numbers of genetic markers and individuals and have led to some promising results in the analysis of even complex traits such as diabetes, asthma, and psychiatric disorders. It is tempting to speculate that, with the increasing emphasis on genetic association studies and fine-mapping data (Cardon and Abecasis, 2003), the next decade will produce similar advances in algorithms for the estimation and analysis of haplotypes . . . , but we will leave that story for the 2nd edition!

Short Specialist Review

Information content in gene mapping

Dan L. Nicolae
The University of Chicago, Chicago, IL, USA

1. Introduction

All genome-wide linkage screens carried out on qualitative and quantitative traits as well as most of the association studies extract only part of the underlying information. Missing information can be the result of different sources, such as absence of DNA samples, missing genotypes, spacing between markers, noninformativeness of the markers, or unknown haplotype phase. The information is never complete in linkage studies but, at least in theory, the amount of missing information can be made arbitrarily low by increasing the number of markers in a region. Knowing how much information is missing from the dataset is important for selecting follow-up strategies and assessing the chances of increasing the significance by reducing the amount of missing information. A related question in linkage studies is the relative efficiency between two ways of increasing information–collecting more families or adding more markers.

There are several measures of information that are used in practice. They can be divided into two main categories. Averaged measures are a function of the data structure and allele frequencies (Botstein *et al*., 1980; Teng and Siegmund 1998; Guo and Elston 1999), and are used to evaluate how informative the data would be. The measures that are conditional on the observed data are a function of the data structure, allele frequencies, and observed genotypes (Kruglyak *et al*., 1996; Nicolae and Kong 2004), and are used to determine the amount of information extracted by the available data. The former measures can be used in designing linkage studies. The latter measures can be used in both the design of the study and of the follow-ups, and in the interpretation of the results.

2. Measures of information

The Polymorphism Information Content (Botstein *et al*., 1980) is defined as the probability to deduce which allele was inherited from a heterozygous parent. They proposed to use this in localizing genes involved in a rare dominant disease, and

they showed that, under Hardy–Weinberg equilibrium,

$$\mathrm{PIC} = \sum_{i=1}^{k} p_i^2 - 2\sum_{i=1}^{k-1}\sum_{j=1}^{k} p_i^2 p_j^2 \tag{1}$$

where p_i is the frequency of the ith allele.

The Linkage Information Content (LIC), introduced by Guo and Elston 1999, is defined as the probability of knowing the number of alleles shared identical by descent (IBD) by a particular pair at a given marker. LIC values are derived for full sib, half sib, grandparent–grandchild, first cousin, and avuncular pairs as a function of the allelic frequencies (Guo and Elston 1999; Guo *et al*., 2002).

In many applications, it is important to measure the information contained in the data, which is relevant for deciding whether certain regions have to be enriched by additional genotyping. Also, the majority of the current genome-wide linkage scans use multipoint calculations (*see* Article 48, **Parametric versus nonparametric and two-point versus multipoint: controversies in gene mapping**, Volume 1) to extract the IBD information from multiple markers. Because the information measures described above are not adequate for these cases, different approaches have been introduced (Kruglyak *et al*., 1996; Nicolae and Kong 2004). In general, the marker information of all the loci on the chromosome is used to calculate a probability distribution on the space of inheritance vectors. For each locus, an inheritance vector is a binary vector that specifies, for all the nonfounding members of the pedigree, which grandparental alleles are inherited. Under the assumption of no linkage of phenotype to the chromosome, all inheritance vectors are equally likely, which leads to a uniform prior distribution on their space. Assuming no interference, a Hidden Markov Model (*see* Article 52, **Algorithmic improvements in gene mapping**, Volume 1) can be used to calculate the inheritance distribution conditional on the genotypes at all marker loci. The distribution of the inheritance vectors conditional on the observed data is the basis of the statistical inference. In particular, this distribution is used to determine the conditional distribution of the number of alleles IBD at a given location.

In general, the data consist of n pedigrees with genotype data on some markers for some pedigree members. For a position t and for pedigree i, let $\omega_i = \omega_i(t)$ denote the inheritance vector. The information content of inheritance vectors was introduced by Kruglyak *et al*. (1996) based on the entropy (Shannon 1948) as

$$I_{\mathrm{E}}^{i} = 1 - \frac{E^i(t)}{E_0^i} = 1 - \frac{-\sum_{\omega_i} P_0(\omega_i|\mathrm{data}) \log_2 P_0(\omega_i|\mathrm{data})}{-\sum_{\omega_i} P_0(\omega_i) \log_2 P_0(\omega_i)} \tag{2}$$

where probabilities are calculated under Mendelian inheritance. This measure of information always lies between 0 and 1, where 1 indicates perfect information and 0 indicates total uncertainty. The definition of the overall information content of a dataset is based on the global entropy, which, summed over all n pedigrees is

defined as

$$I_{\mathrm{E}} = 1 - \frac{E(t)}{E_0} = 1 - \frac{\sum_{i=1}^{n} E^i(t)}{\sum_{i=1}^{n} E_0^i} = \frac{\sum_{i=1}^{n} E_0^i I_{\mathrm{E}}^i}{\sum_{i=1}^{n} E_0^i} \quad (3)$$

Thus, the global information is a weighted average of the family information with weights proportional to E_0^i. These weights depend on the family size; they are equal to the dimension of the inheritance vector for the corresponding family. Note that this measure does not depend on the linkage test used. This might be a disadvantage when the linkage test statistic is a function of the IBD process as I_{E} can be smaller than 1 even if the IBD pattern is known with certainty.

The "model-free" linkage analysis (*see* Article 48, **Parametric versus non-parametric and two-point versus multipoint: controversies in gene mapping**, Volume 1) usually involves a scoring function that is defined on the basis of the IBD sharing among the affected individuals at locus t, $S_i(t)$. In general, the scoring function $S_i = S_i(t)$ can be any function that has a higher expected value under linkage than no linkage. The standardized form of S_i is defined as

$$Z_i = \frac{S_i - \mu_i}{\sigma_i} \quad (4)$$

where $\mu_i = E(S_i|H_0)$ and $\sigma_i^2 = \mathrm{Var}(S_i|H_0)$ are calculated under the null hypothesis of no linkage. The test for linkage can be done using a linear combination

$$Z = \frac{\sum_{i=1}^{n} \gamma_i Z_i}{\sqrt{\sum_{i=1}^{n} \gamma_i^2}} \quad (5)$$

where $\gamma_i \geq 0$ are the weighting factors assigned to the individual families.

In general, information on descent is incomplete and the Z_i's, and hence Z, are not fully determined by the data. The test statistics are calculated on the basis of the probability distribution over the space of inheritance vectors conditional on the genotypes. The missing information can be handled using an artificial likelihood construct, namely, exponential tilting (Kong and Cox 1997)

$$P_\delta(Z_i = z) = P_0(Z_i = z)c_i(\delta)\exp(\delta\gamma_i z) \quad (6)$$

where $c_i(\delta)$ is the renormalization constant. The evidence for linkage is summarized by a lod score that is defined as

$$\mathrm{lod} = \frac{l(\hat{\delta}) - l(0)}{\log(10)} \quad (7)$$

where $\hat{\delta}$ denotes the maximum likelihood estimator for δ.

Let Z(δ) denote the value of the complete information standardized score 5 that leads to a maximum likelihood estimate equal to δ. Note that, in the case of complete IBD information, there is a monotonic one-to-one correspondence between the sufficient statistic Z, the maximum likelihood estimate of δ, and the lod score (*see* Article 56, **Computation of LOD scores**, Volume 1). Let $\text{lod}^*(Z = Z(\hat{\delta}))$ be the exponential lod score calculated assuming complete information exists and assuming that the maximum likelihood estimate of δ is the same as the one obtained with partial information. This lod score can be interpreted as the predicted lod score in the case of complete information. The difference between the observed lod score and the predicted lod score can be interpreted as the amount of missing information in the data

$$\text{RI}_\text{P} = \frac{\text{lod}}{\text{lod}^*(Z = Z(\hat{\delta}))} \tag{8}$$

and can be used as a measure of relative information (Nicolae and Kong 2004). It is bounded between 0 and 1, equaling 1 in the case of complete information, and it is natural to define it as 0 in the case of total uncertainty (note that both lods are equal to zero when the data are totally uninformative and the value of the measure in this case is obtained by taking a limit). This measure is conditional on the observed data and is dependent on the test statistic used in the linkage test. Follow-up strategies can be designed using this measure. For example, suppose we are interested in a given location with $\text{RI}_\text{P} = 0.5$. The lod score will double if we add markers that make the IBD process known, and the value of the maximum likelihood estimate of δ does not change. Also, the lod score will double if we double the number of families such that the sharing signal and the information is the same in the additional families as it was in the original families.

Likelihood-based measures of relative information can be applied to other areas of gene mapping. For example, consider haplotype-based case-control association studies (*see* Article 12, **Haplotype mapping**, Volume 3). The test for identifying haplotype groups that confer different risks can be done using likelihood ratio statistics on well-chosen models (Gretarsdottir *et al*., 2003). Let Λ denote the likelihood ratio statistic calculated from the genotype data and Λ^* denote the likelihood ratio statistic that would have been obtained assuming no uncertainty in the haplotype counts and that the maximum likelihood estimates stay the same. To measure the relative information, one can use (Nicolae and Kong 2004)

$$\text{RI}_\text{H} = \frac{\Lambda}{\Lambda^*} \tag{9}$$

The value of $1 - \text{RI}_\text{H}$ is a measure of the proportion of information missing due to uncertainty with phase and/or missing genotypes.

The LIC values are implemented in a software called POLYMORPHISM (Niu *et al*., 2001). The entropy-based measure I_E can be calculated using GENEHUNTER (Kruglyak *et al*., 1996). The RI_P measure is implemented in the software ALLEGRO (Gudbjartsson *et al*., 2000). The information content in haplotype association studies, RI_H, can be calculated with NEMO (Gretarsdottir *et al*., 2003).

Short Specialist Review

Sex-specific maps and consequences for linkage mapping

Solveig K. Sieberts
Rosetta Inpharmatics LLC, Seattle, WA, USA

Daniel F. Gudbjartsson
deCODE Genetics, Reykjavík, Iceland

1. Introduction

From the beginning of linkage mapping, differential recombination rates have been observed in the sexes (Haldane, 1922; Huxley, 1928). In the extreme case, Drosophila males exhibit no recombination during meiosis (Morgan, 1914), while females do. In most other species for which linkage maps exist, this sex difference is more moderate. For mammals, excluding humans, published genome-wide female-to-male ratios of genetic map distances vary between 1.55 : 1.0 and 1.0 : 1.2, with a typical lengthening of female map with respect to the male map (Barendse *et al*., 1994; Dietrich *et al*., 1996; Mikawa *et al*., 1999; Neff *et al*., 1999; Maddox *et al*., 2001). The exceptions include bovine, for which there appears to be no sex difference (Barendse *et al*., 1994), and sheep, for which there is a higher recombination rate in males than in females (Maddox *et al*., 2001).

2. Sex-specific maps in humans

In humans, females also tend to show an increase in recombination relative to males. This was first demonstrated by Renwick and Schulze (1965) and has been verified through the construction of genome-wide sex-specific genetic maps (Donis-Keller *et al*., 1987; Broman *et al*., 1998; Kong *et al*., 2002). The deCODE map, which is the most recent human genetic map, to date, estimates the overall female-to-male map distance ratio to be 1.65 : 1.0. The distance ratio varies by chromosome from 1.34 : 1.0 to 1.80 : 1.0 for chromosomes 19 and 11, respectively (Kong *et al*., 2002), with typically higher values on longer chromosomes.

Relative sex-specific distances are not constant throughout the genome. Figure 1 shows the relative map difference as a function of location for chromosomes 4, 10, 13, and 16. The relative map difference (Matise *et al*., 1993) is a transformation

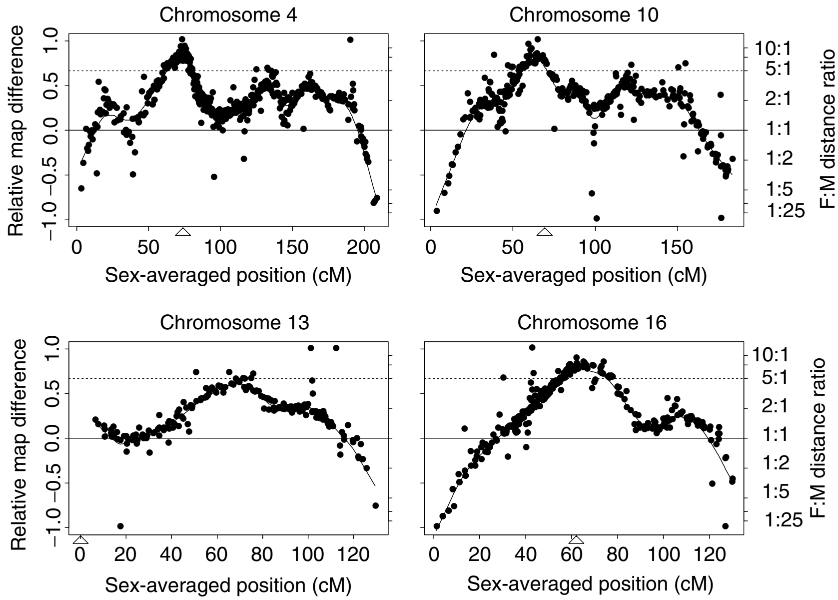

Figure 1 For chromosomes 4, 10, 13, and 16, the relative difference (q) between female and male map distances for all possibly overlapping marker intervals with lengths between 0 and 25 cM. The relative difference is plotted versus the sex-averaged midpoint of the marker interval. The deCODE framework markers are used for interval length calculation. These consist of 66, 55, 34, and 41 markers on chromosomes 4, 10, 13, and 16 respectively. The solid line is a smoothing of the points and the triangle indicates the approximate location of the centromere

of the map distance ratio and is defined by

$$q = \frac{d_f - d_m}{d_f + d_m} = \frac{d_f/d_m - 1}{d_f/d_m + 1}$$

where d_f and d_m are the female and male distances respectively. This measure is used because it always takes values in the range $[-1, 1]$, whereas the ratio, d_f/d_m can take values in the range $[0, \infty)$. Positive values of q indicate female-to-male ratios greater than 1 and negative values indicate female-to-male ratios less than 1. In Figure 1, the relative differences are plotted versus the sex-averaged position for the center of the interval, for all possible intervals with length between 0 and 25 cM, in order to reveal the pattern of distance ratio along the chromosome. A general trend toward greater distances in females than in males is evident. The relative map difference varies greatly along the chromosome and patterns of sex differences vary between chromosomes. Typically, the telomeric regions tend to exhibit more recombination in males than in females. The regions surrounding the centromeres often exhibit the highest female recombination rates, relative to the male rates. Broman *et al*. (1998) speculate that peaks in relative female recombination rate, which do not coincide with the presence of a centromere, may be due to the presence of suppressed latent centromeres. The patterns of

sex-specific recombination may explain the trend toward higher chromosome-wide female-to-male distance ratios on longer chromosomes, because the telomeric regions of increased male recombination comprise relatively smaller portions of the chromosome. These patterns also suggest that true genome-wide female-to-male ratios may be overestimated because of the lack of markers, and thus map distance estimates, near the telomeres where male recombination is relatively more frequent.

Map distance ratios in smaller regions can be quite extreme. For example, the deCODE genetic map shows marker intervals with sex-averaged map distances up to 3.98 cM (female distance 7.95 cM) for which the male distance is estimated to be zero. Similarly, there are regions with sex-averaged distances up to 3.55 cM (male distance 7.09 cM) for which the female distance is estimated to be zero. If we restrict ourselves to regions greater than 5 cM, there are still several instances of female-to-male ratios greater than 25 : 1 and less than 1 : 25, and most chromosomes exhibit at least one region with ratios more extreme than 10 : 1 or 1 : 10. On chromosome 20, this region is almost 25-cM long. Many chromosomes exhibit large segments with ratio greater than 5 : 1, typically surrounding the chromosome's centromere. These segments, which are identified by q values greater than 2/3, can be observed in Figure 1 and can be over 40-cM long.

3. Consequences for linkage analysis

Despite the differences in sex-specific maps, most linkage analyses assume sex-averaged maps. Daw *et al*. (2000) showed that for backcross data (i.e., fully informative meioses at all loci, including the trait), falsely assuming a sex-averaged map caused a negative bias in LOD score when linkage truly exists. This bias is typically quite small. For example, for a trait located midway between two markers, spaced 10 cM apart, falsely assuming a sex-averaged map causes an LOD score bias of −0.001 when the true female-to-male distance ratio is 5 : 1. This is quite small relative to the expected LOD (ELOD) under the true map, which is 0.265. The amount of bias increases as the true sex-ratios become more extreme and as the intermarker distances increase.

For an unlinked trait, the bias is positive. In this case, the bias is much larger both in absolute value and relative to the ELOD. For example, for a 10-cM interval with sex ratio 5 : 1, the ELOD under the correct map at a locus midway between the two markers is −1.028 and the bias that results from assuming a sex-averaged map is 0.118. In the unlinked case, the bias increases as the true sex-ratios become more extreme but decreases with increasing marker interval. The authors concluded that assuming a sex-averaged map causes only a slight reduction in power. However, it causes a modest increase in false-positive rate. These authors assumed a special case (i.e., fully informative meioses at all loci, including the trait), which is typically not the type of data available for humans.

In practice, meioses at marker loci are often not fully informative and meioses at the trait locus are rarely fully informative. In this case, the genetic map is especially important because it indicates the dependence between meioses at different loci. When meioses at a particular locus are not completely informative, multipoint linkage analyses incorporate information from other linked loci to increase the

Table 1 Distribution of parametric LODs[a], assuming either the true map or the sex-averaged map when the true map is a sex-specific map with F : M ratio 5 : 1

		Linked			Unlinked		
Pedigree	Map[b]	ELOD (SD)	$P(>3)$	$P(<1)$	ELOD (SD)	$P(<-2)$	$P(>1)$
Sibs	SS	2.79 (1.49)	0.44	0.12	−3.01 (1.68)	0.73	8.4×10^{-3}
	SA	2.81 (1.50)	0.45	0.11	−3.03 (1.69)	0.73	8.5×10^{-3}
Hsib (f)[c]	SS	1.23 (0.98)	0.04	0.41	−1.35 (1.31)	0.28	0.02

information. Misspecifying the genetic map causes the dependence between the markers to be misspecified and, thus, affects the imputations at each locus. As a result, assuming a sex-averaged map can have different consequences than in the backcross case, where the map is used only to specify the expected number of recombinations against which the observed number is compared.

Tables 1 and 2 demonstrate the effects of assuming a sex-averaged map in cases in which meioses are not fully informative. Three different affected relative pairs are used: full sibs, half sibs where the common parent is a female [hsib (f)], and half sibs where the common parent is a male [hsib (m)]. In each case, the parental data was assumed to be missing. Marker data was assumed at two loci, each with four equifrequent alleles. The sex-averaged intermarker spacing was 10 cM,

and the female-to-male map distance ratio was 5 : 1. A fully dominant trait locus with allele frequency 0.1 was assumed to be positioned either midway between the markers or unlinked. Table 1 shows exact ELODs and standard deviations of LODs for parametric computations under the true map and sex-averaged map. These computations show that assuming sex-averaged maps can cause positive or negative bias in the LOD score. When the pedigree contains equal numbers of male and female meioses, as is the case for full sibs, falsely assuming a sex-averaged map can cause a small inflation in the ELOD, when the trait is linked, and a small decrease in the ELOD when the trait is unlinked. In both the linked and unlinked cases, for a single sibpair, the median LOD score is slightly larger under the sex-specific map than under the sex-averaged map. The probability of a significant or suggestive LOD is slightly increased under the sex-averaged map, both when the trait is linked or unlinked. The probability of excluding linkage,with LOD scores less than −2, is also slightly increased under the sex-averaged map in both the linked and unlinked case. In the case of half sibs, the number of male and female meioses are different, so the effects can be more extreme. In fact, the relevant meioses in these pedigrees are either solely the male meioses or solely the female meioses, depending on which parent is shared by the affected individuals. As a result, assuming a sex-averaged map has the same effect as assuming a map that is strictly too long or too short. When the affected relative pairs are half sibs with a common mother, all meioses, which are informative for linkage, are female meioses and the sex-averaged map is too short. This causes a negative bias in the LOD score in both the linked and unlinked cases, which results in reduced power to detect suggestions of linkage when the trait is linked. When the affected pair share a common father, the sex-averaged map is too long. The resulting sex-averaged LOD score shows positive bias, but because the variance is reduced, the probability of a significant LOD score is actually slightly reduced.

Table 2 shows the effects of assuming a sex-averaged map on NPL scores (Kruglyak *et al*., 1996) and allele-sharing Z_{LR} scores (Kong and Cox, 1997). The Z_{LR} is the signed square root of the allele-sharing likelihood ratio, and thus is equal to approximately 2.15 times the signed square root of the allele-sharing LOD score. This statistic, like the NPL score, is asymptotically normally distributed. In the linked case, the expectation of the Z_{LR} behaves similar to the LOD in the parametric case, but the standard deviation is barely affected. The NPL score shows different patterns. When the affected individuals are half sibs with a common mother, the sex-averaged map causes an increase in NPL over the sex-specific map NPL, and when the half sibs share a common father, the NPL under the sex-averaged map causes a decreased NPL score. Note that difference in the sign of the bias between the NPL and the other test statistics is driven by the bias in the standard deviation. If the NPL statistic were normalized, so that standard deviation were truly 1 under the null hypothesis, as assumed, the bias sign would match the bias sign of the other two statistics. When the trait is unlinked, both the Z_{LR} and NPL exhibit small amounts of bias under sex-averaged maps. However, the standard deviation of the NPL is affected by the map misspecification, while the standard deviation of the Z_{LR} is not. In the case of half sibs sharing a mother, the standard deviation is higher under the sex-averaged map. Because NPL tests falsely assume a null distribution with variance 1, in this case, the use of the

sex-averaged map results in a test that is less conservative than under the true map. When the shared parent is a father, the standard deviation is smaller under the sex-averaged map, which causes an already conservative test to be more conservative.

The amount of bias caused by map misspecification is affected by several factors. The bias increases with marker spacing. For example, using the hsib (m) pedigrees, the bias in Z_{LR} for a pair of markers spaced 2 cM apart is 0.03 for an unlinked trait. For a marker at a 10-cM spacing, the bias is 0.09. The bias also increases with marker number and marker density. Six markers with 2-cM intermarker spacing, thus spanning 10 cM, yield a bias of 0.27 when the trait is unlinked. Six markers at a 10-cM intermarker spacing yield a bias of 0.41 when the trait is unlinked. The number of alleles, and thus the marker information, also affects the amount of bias. The more informative the markers, the greater the bias. For two markers with eight equifrequent alleles, the bias is 0.23, when the trait is unlinked and the markers are spaced 10 cM apart. Finally, the sample size affects the amount of bias. Parametric LOD scores are additive across families, so the amount of bias increases linearly with the number of families. Doubling the number of families doubles the bias. Both the NPL and the Z_{LR} are constructed to have fixed variance under the null hypothesis. The NPL is scaled by the complete-data standard deviation and the Z_{LR} is constructed to have an asymptotic variance of 1. As a result, the bias of both of these statistics scales as the square root of the number of families. Thus, quadrupling the sample size doubles the bias.

Typically, the difference in number of male and female meioses will be more moderate than in the half sib case. In most practical cases, the use of sex-averaged maps will not significantly affect the results of linkage analyses. Still, the danger of bias in multipoint linkage analysis exists in certain situations. This bias becomes more extreme as the number of linked markers and marker informativeness increase. Analyses with sex-specific maps should be done to verify signals that occur in areas of extreme sex-distance ratios or when the signal is driven by pedigrees with unequal numbers of male and female meioses. Loss of power can also be an issue, but strategies to prevent this situation are more difficult. Another instance, when the use of sex-specific maps is particularly important, is when modeling parent-of-origin effects, such as in imprinting models (Hanson *et al*., 2001; Shete and Amos, 2002; Karason *et al*., 2003). Mukhopadhyay and Weeks (2003) found that using sex-specific maps could cause significant change in variance component LOD scores for an imprinting model. In most instances, the use of a sex-specific map increased the LOD score, although they reported one instance of a decrease in LOD score. At several loci, the LOD score assuming the sex-averaged map was insignificant, but was significant under the sex-specific map. Linkage analyses assuming sex-specific maps can be performed in many linkage packages including ALLEGRO (Gudbjartsson *et al*., 2000), FASTLINK (Cottingham *et al*., 1993), LINKAGE (O'Connell and Weeks, 1995), Loki (Heath, 1997), S.A.G.E. (S.A.G.E., 2002), and VITESSE (O'Connell and Weeks, 1995). These packages span a variety of different types of linkage analyses. As of the current date, sex-specific maps are not implemented in GENEHUNTER (Kruglyak *et al*., 1996).

Polymorphic inversions, deletions, and duplications in gene mapping

Susan L. Christian
University of Chicago, Chicago, IL, USA

One of the under recognized complexities of gene mapping is the presence of chromosomal anomalies (*see* Article 11, **Human cytogenetics and human chromosome abnormalities**, Volume 1) within the human genome. Inversions, deletions, and duplications have the effect of disrupting linkage or association analyses by complicating genetic mapping of a region (inversions) or overlooking a disease gene caused by either a deletion or duplication. An understanding of the underlying architecture of the human genome that causes these anomalies is needed to accurately assess the data acquired through linkage or association analyses.

One unexpected structural feature identified following sequencing of the human genome was the presence of segmental duplications (SDs) (*see* Article 26, **Segmental duplications and the human genome**, Volume 3) that mediate chromosomal rearrangements. Segmental duplications are defined as stretches of genomic DNA that are >1 kb in length with >90% sequence identity that map to multiple regions (Eichler *et al.*, 2004). These regions are normal stretches of genomic DNA containing transcriptionally active genes that have undergone duplication as part of evolution of the human genome (Bailey and Eichler, 2003). SDs comprise ~5% of the genome with a frequency of 1–14% among the 24 chromosomes (Zhang *et al.*, 2005). The distribution of SDs varies between chromosomes with preferential location in pericentromeric and subtelomeric locations (Eichler *et al.*, 2004; Zhang *et al.*, 2005).

The presence of these SDs has posed a major problem in mapping and sequencing of the human genome. The latest release of the human sequence in October 2004 stills shows 341 gaps, many of which either contain or are flanked by SDs (IHGSC, 2004). Additionally, the larger SDs (>100 kb) and those with >99% sequence identity complicated the sequencing of the human genome such that regions containing SDs were merged together or otherwise misassembled (Cheung *et al.*, 2003; Eichler *et al.*, 2004). This problem was exacerbated by the whole-genome shotgun sequencing approach used by Celera that relied on sequencing of small stretches of DNA followed by assembly (She *et al.*, 2004).

The presence of SDs within the human genome has also complicated the development of single nucleotide polymorphisms (SNPs) (*see* Article 50, **Gene**

mapping and the transition from STRPs to SNPs, Volume 1). The goal in the development of SNPs was to find sequence variation at a single nucleotide position within the genome. With the presence of SDs, a putative SNP may actually represent sequence variation between two different copies of an SD present at separate loci within the genome. An examination of SNPs validated for a single locus showed an underrepresentation in SDs where 3.75% of validated SNPs versus 13.1% of nonvalidated SNPs were identified in the 4.5% of the genome composed of SDs (Fredman *et al*., 2004). Therefore, validation of SNPs is essential to prevent usage of variants located in SDs that represent paralogous copies from other chromosomes rather than a true SNP.

An additional problem with the presence of SDs is the propensity of these regions to misalign during meiosis, producing chromosomal inversions, deletions, and duplications (*see* Article 13, **Meiosis and meiotic errors**, Volume 1 and Article 17, **Microdeletions**, Volume 1). When SDs arranged in an inverted orientation align with each other, the single copy region between them is inverted. Inversions do not change the copy number of genomic DNA but may disrupt genes at the breakpoints. Several disorders have been identified on Xq28 that are thought to arise during male meiosis where the single X folds back on itself and rearranges at the sites of SDs causing inversions. Additionally, carriers of inversions may produce offspring with unbalanced karyotypes associated with severe abnormalities. One example is a submicroscopic 8p inversion that is present in 26% of a population of European descent (Giglio *et al*., 2001). Females with this inversion had children with three different types of abnormalities of 8p including an interstitial deletion associated with a heart defect, a derivative marker 8p associated with a distinct phenotype plus an inverted duplication 8p chromosome with minor anomalies (Giglio *et al*., 2001).

The alignment of a chromosomal region containing an inversion during meiosis forces one homolog to form a loop to pair with the other homolog. Any rearrangement within this loop will produce unbalanced offspring. Only the unchanged normal and inverted homologs will produce a normal chromosomal complement. Thus, individuals heterozygous for an inversion would appear to show reduced recombination because of the dosage imbalance produced in the gametes.

As marker maps used in linkage mapping become denser, polymorphic inversions such as the 8p inversion described above may add to the challenges of linkage mapping. In the case of polymorphic inversions, different individuals actually have different genetic maps at the site of the inversion. Conducting linkage analysis assuming the marker order of the most common of the inversion orientations can lead to a falsely inflated estimate of local recombination frequencies and/or increases in the genotyping error rates. This is because a single recombination that occurs between informative markers within the inverted segment in an individual homozygous for the rarer orientation will be interpreted as a set of three recombination events in genetic intervals that are very close together. Of course, the apparent increase in recombination frequency and genotyping error would be even worse if the analysis is conducted assuming a marker order consistent with the less common orientation of the inversion. The basic problem is that either orientation will create apparent recombination events (often interpreted as genotyping error) because there are actually multiple maps within the population.

Reciprocal deletions and duplications occur when SDs arranged in a direct orientation undergo homologous recombination. In this case, one copy of the region between the SDs is translocated from one homolog to the other, producing a loss on one homolog and a gain on the other. Many human diseases are now recognized that are caused by these rearrangements between SDs including Charcot-Marie-Tooth disease type 1A and hereditary neuropathy with liability to pressure palsies due to a reciprocal duplication/deletion rearrangement on 17p11.2 (Shaw and Lupski, 2004).

Genotyping data of a region containing a deletion will appear as a contiguous stretch of homozygous markers including some with non-Mendelian inheritance from a single parent. Also, a deletion cannot be distinguished from a case of uniparental isodisomy (*see* Article 19, **Uniparental disomy**, Volume 1) where there are two identical copies of a chromosomal region present from a single parent. Duplications are sometimes more difficult to identify. In linkage analysis involving microsatellite markers, a duplication may appear as the presence of three alleles with equal intensity or two alleles with double dosage of one allele. Most software programs designed to assign microsatellite genotypes do not anticipate this situation and read only the first two alleles. In cases with three alleles, the data will be read as the presence of two maternal alleles in 2/3 of the instances rather than reading all three alleles. Therefore, microsatellite data across a duplication would show the presence of a mixture of uninformative single alleles plus some with biparental inheritance and others with apparent uniparental heterodisomy showing two different alleles from a single parent. With the dense SNP maps being used in linkage analysis, such regions may be characterized by clusters of markers with higher than average numbers of Mendelian incompatibilities.

Whole-genome association studies using SNP arrays also have the potential to identify genomic imbalances. In one study, cell lines with 1–5 X chromosomes were analyzed using a 10K SNP array to detect DNA copy number (Zhao *et al*., 2004). Comparisons were made with a pool of normal DNA and the log 2 ratios computed. In all cases, the inferred copy number matched the known X chromosome copy number. Additional studies involving cancer cell lines also detected both deletions and duplications that were confirmed by quantitative PCR.

With SDs comprising ~5% of the genome, the potential for chromosomal rearrangements between them is vast. Many benign polymorphisms (*see* Article 10, **Measuring variation in natural populations: a primer**, Volume 1) are likely to be present in addition to anomalies that will provide susceptibility to human disease. The identification of chromosomal imbalances that are part of the normal variation within humans is currently under study. Sebat *et al*. (2004) surveyed 50 Mb in 20 normal individuals using representational oligonucleotide microarray analysis (ROMA). In this method, a reduced complexity library of Bgl II DNA was developed to identify 85 000 probes in a size range of 200–1200 bases that were spaced 1/35 kb across the genome. Seventy-six unique copy number polymorphisms were identified with an average of 11 per individual.

In another study using array comparative genomic hybridization (*see* Article 23, **Comparative genomic hybridization**, Volume 1), Iafrate *et al*. (2004) surveyed 300 Mb in 55 unrelated individuals. Thirty-nine were unrelated apparently healthy controls and 16 had known abnormalities. Two hundred and twenty-six copy number polymorphisms were identified. One hundred and two were found in two or

more individuals and 24 in >10%. On average, 12.4 copy number polymorphisms were observed per individual.

The question then becomes whether the genomic imbalances detected represent benign polymorphisms or susceptibility to human disease. The answer will most likely be a mixture of both. For inheritance of common diseases such as diabetes or psychiatric disorders, the presence of multiple susceptibility loci that provide small effects (*see* Article 58, **Concept of complex trait genetics**, Volume 2) has long been a hypothesis for the genetic mechanism of disease. The primary effort has focused on the identification of variation at the nucleotide level in specific genes as the bases for these susceptibilities. However, the presence of these larger deletion/duplication variants mediated by SDs may also represent another class of small effect loci that affect susceptibility to common disease.

Short Specialist Review

Impact of linkage disequilibrium on multipoint linkage analysis

Christopher I. Amos

U.T.M.D. Anderson Cancer Center, Houston, TX, US

Qiqing Huang

Johnson & Johson Pharmaceutical Research and Development, Raritan, NJ, US

In multipoint linkage analysis, when there is unresolved phase information for multiple heterozygous individuals, equal probabilities are usually assigned to all possible phases that are compatible with the data (O'Connell and Weeks, 1995; Kruglyak *et al*., 1996). Currently, all implementations of the Lander-Green algorithm, which are commonly used for most multipoint linkage applications, such as Allegro (Gudbjartsson *et al*., 2000), and Genehunter (Kruglyak *et al*., 1996), assume linkage equilibrium among the markers. This is a reasonable assumption for sparsely spaced markers (e.g. ∼10 cM microsatellite markers) since the markers would not be expected to show LD at this distance. However, this assumption can be problematic when there is strong LD among tightly linked markers, because LD causes the observed haplotype frequencies to deviate from the expected haplotype frequencies, and results in inaccurate phase probabilities.

When parental genotype data are available, linkage calculations use the observed genotypes rather than specified genotype frequencies. In this situation, linkage analysis is robust to misspecification of phase probabilities (Ott, 1999). However, when some of the parental data are missing, for example, for late-onset diseases (LOD), the linkage equilibrium assumption can lead to a severe bias for tightly linked markers (Huang *et al*., 2004; Boyles *et al*., 2005).

Schaid *et al*. (2002) showed with an example that assuming linkage equilibrium in pedigree-based haplotype inference produced highly inaccurate haplotype frequencies from population based EM estimation. They found that haplotype frequencies inferred by pedigree analysis programs are close to the expected frequencies under an assumption of equal phase probabilities. Huang *et al*. (2004) studied the impact of linkage equilibrium assumption on multipoint linkage statistics when there is strong LD between markers. They showed both analytically and by simulation that assuming linkage equilibrium between tightly linked markers could lead to false- positive linkage signals when some of the parental data are

missing. Boyles *et al*. (2005) further extended the results of Huang *et al*. (2004) by simulation and found that the squared correlation between markers is a better indication of potential for spurious inflation of LOD scores than the standardized disequilibrium coefficient. In addition, they found that markers that show negative LD do not lead to inflation of the LOD score (in part because the squared correlation is low between such markers).

LD between tightly linked markers causes certain haplotypes to be more frequent than expected underlinkage equilibrium. The accrual of those haplotypes in families selected through affected relatives may be misinterpreted as oversharing of multipoint IBD, if the phases have been incorrectly specified (for example, because the linkage program assumes equal phase probabilities). The biased interpretation of IBD sharing among relatives will generate false- positive evidence of linkage for affected sib-pair analysis using model-free linkage methods. Similarly, for parametric linkage analysis, if there are only affected sib-pairs and parental data are missing, the accrual of certain haplotypes within a subset of families may also appear to indicate evidence of linkage to the disease. Linkage analysis under a heterogeneity model will lead to an excess of false-positive results (Figure 1 of Huang *et al*., 2004).

Single point linkage analysis (parametric and model-free) does not suffer from this bias, although it does require accurate marker allele frequency estimates at each locus if the families have been selected through affected sibling pairs (Williamson and Amos, 1995). Bias can also be eliminated with parental data and reduced with additional unaffected sibs.

Recently, there is increasing interest in using high-density single-nucleotide-polymorphism (SNP) markers for linkage analysis instead of traditional panels of microsatellite markers (Middleton *et al*., 2004; John *et al*., 2004; Schaid *et al*., 2004). Evans and Cardon (2004) showed that a SNP map of 1 SNP/cM is sufficient to extract most of the inheritance information (>95% in most cases) when parental genotypes are available and much higher density SNP markers are needed when some of the parental data are missing.

Although high-density SNP markers can provide more information than sparse microsatellites, caution should be exercised when evaluating evidence of linkage with dense markers since strong LD may exist between some of the markers. The apparent evidence of linkage may reflect an excess of false-positive linkage results due to LD between the tightly linked markers. To reduce false-positive evidence for linkage, Webb *et al*., (2005) have introduced software that evaluates the LD among sets of markers and then drops any markers that show LD among a user-defined threshold. But this may decrease the information content and reduce the power. In addition, with very dense panels of markers, we have found that just applying a pairwise-test for LD among markers may not completely protect against false-positive results. Bacanu (2005) suggested dividing dense mapping panels into sets of disjoint but overlapping markers. Results of linkage on these disjoint panels can then be averaged and the estimate of variance among panels provides a statistic that can be used to construct hypothesis tests.

Alternatively, a version of Merlin has been developed (Abecasis *et al*., 2002; Abecasis and Wigginton, 2005) that uses haplotypes rather than alleles at clusters of tightly linked markers. The definitions of the clusters can be either user-defined

or automatically generated, by using an R-squared criterion for LD among the marker loci. Within a cluster, haplotype frequencies are estimated by an application of the E-M algorithm and then the linkage analysis uses haplotypes, weighted by their probabilities, rather than genotypes. Application of this approach to simulated data showed a mild loss of information by clustering markers into haplotypes but protection from false-positive linkage findings. Many existing parametric linkage procedures that use the Elston-Stewart algorithm such as Linkage (Lathrop and Lalouel, 1988) can incorporate haplotype probabilities but implementation is currently awkward when considering more than a few loci jointly.

Basic Techniques and Approaches

Computation of LOD scores

Anthony L. Hinrichs and Brian K. Suarez
Washington University in St. Louis, St. Louis, MO, USA

1. Introduction

In this section, we will demonstrate detailed examples of linkage calculations for various types of data. Our initial examples will be of parametric analysis for Mendelian traits. This will be followed by an example using Affected Sibling Pair (ASP) methods. Finally, we will compute a nonparametric linkage (NPL) score using Whittemore–Halpern statistics for the same dataset. We will assume that the reader is already familiar with recombination, genetic map distances, identity by descent measurement, and likelihood (*see* Article 49, **Gene mapping, imprinting, and epigenetics**, Volume 1, Article 50, **Gene mapping and the transition from STRPs to SNPs**, Volume 1, and Article 51, **Choices in gene mapping: populations and family structures**, Volume 1).

2. Parametric linkage – dominant disorder

We will begin with an example adapted from Suarez and Cox (1985) (Figure 1). In this case, the sample phenotype is fully penetrant Mendelian dominant. Since individual I-1 is affected, we know that individual I-1 carries at least one copy of the disease allele. Since there is at least one unaffected offspring, we know that individual I-1 does not carry two copies of the disease allele. In the case of no unaffected offspring, the following calculations would be weighted by the probability that the affected founder carries two copies of the disease allele.

As presented in Article 48, **Parametric versus nonparametric and two-point versus multipoint: controversies in gene mapping**, Volume 1, a parametric LOD score (Barnard, 1949) for a recombination rate of θ is computed as

$$\log_{10}\left(\frac{L(\theta)}{L(0.5)}\right)$$

Because phase between the marker alleles and the disease allele is unknown in individual I-1, we must condition on the phase using a uniform prior. There are 19 descendants of individual I-1 who had a chance of receiving the disease allele (since individual II-5 is unaffected, her offspring carry no information). Since all pairs of

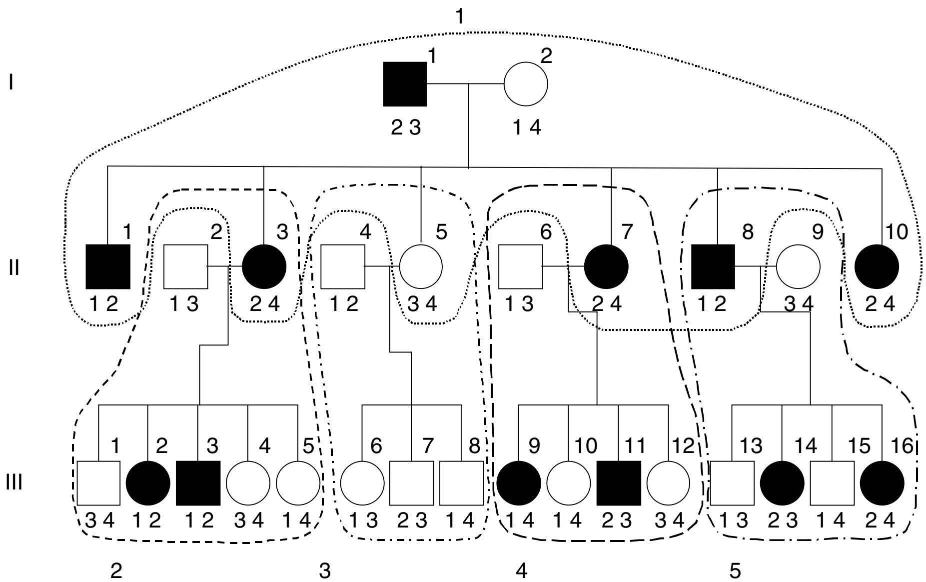

Figure 1 Fully penetrant Mendelian dominant phenotype. Pedigree members are numbered by generation and sequentially within a generation. The numbers below the pedigree symbols are the individuals' genotype. The dashed and dotted lines separate the five nuclear families that comprise the larger pedigree

parents have 4 unique markers (so all meioses can be directly observed), we directly observe 19 recombination/nonrecombination events for each of the two possible phases. If the disease allele is linked to marker 2 in individual I-1, then we observe 1 recombination (in individual III-9) and 18 nonrecombinations. If the disease allele is linked to marker 1 in individual I-1, then there are 18 recombinations and 1 nonrecombination. Then for any recombination fraction θ, we have

$$L(\theta) = \frac{1}{2}\left(\theta(1-\theta)^{18} + \theta^{18}(1-\theta)\right) \tag{1}$$

The LOD score for disease locus at the marker locus is undefined; we observe a recombination so the likelihood is 0. However, we can compute the maximum likelihood estimator (MLE) for θ by solving

$$\frac{\mathrm{d}L}{\mathrm{d}\theta} = 0 \tag{2}$$

Solving numerically, we find the maximum at $\theta = 0.0526$. For this recombination fraction, the LOD score is $\log_{10}(L(.0526)/L(0.5)) = 3.717$.

We will next demonstrate the advantage of extended pedigrees. If we divide the pedigree in Figure 1 into nuclear pedigrees, there are four pedigrees with affected individuals with recombination/nonrecombination counts of 6/0, 5/0, 3/1, and 4/0 or 0/6, 0/5, 1/3, and 0/4. For a given recombination fraction, the overall likelihood

of all of the pedigrees is

$$L^*(\theta) = \left(\tfrac{1}{2}\right)^4 \left((1-\theta)^6 + \theta^6\right)\left((1-\theta)^5 + \theta^5\right) \times \left(\theta(1-\theta)^3 + \theta^3(1-\theta)\right)\left((1-\theta)^4 + \theta^4\right) \quad (3)$$

This is simply the product of the likelihoods for each pedigree considered separately. The leading coefficient is $(1/2)^4$ since for each of the four pedigrees we must assume a uniform prior on phase. If we take the derivative as before, we find that the maximum occurs at $\theta = 0.0530$. For this recombination fraction, the LOD score is $\log_{10}(L^*(.0530)/L^*(0.5)) = 2.815$. We note that although $L(0.5) = L^*(0.5)$, the numerator of L^* has decreased owing to the extra ambiguity of phase. For small θ, the difference is the equivalent of three phase-known meioses:

$$L(\theta) - L^*(\theta) \approx 3\log_{10} 2 \approx 0.9$$

This cost of $\log_{10}2$ is paid for each ambiguous phase. By using the entire pedigree at once, we only have one conditional phase. In this case, the whole is greater than the sum of its parts.

3. Parametric linkage – recessive disorder

Our next example is a fully penetrant Mendelian recessive trait (Figure 2). Since the parents are unaffected but have affected children, we know that each carries one copy of the disease allele. As before, we look at recombinations but in this case we are concerned with the phase separately for two disease allele–bearing haplotypes (one in each parent). Furthermore, we cannot be sure whether the unaffected

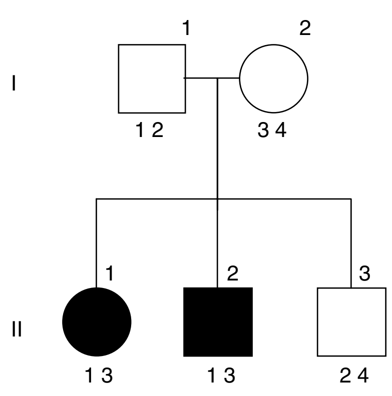

Figure 2 Fully penetrant Mendelian recessive phenotype. Pedigree members are numbered by generation and sequentially within a generation. The numbers below the pedigree symbols are the individuals' genotype

offspring (II-3) carries 0 or 1 copy of the disease allele. We, therefore, must put a uniform prior on the possibilities for recombinations for the unaffected offspring. Out of the four possibilities, one would give the unaffected offspring two disease alleles. Thus, we have 12 possibilities for the six recombination/nonrecombination events:

$$L(\theta) = \frac{1}{12}\left[\begin{array}{c}(1-\theta)^6 + 2\theta(1-\theta)^5 + 2\theta^2(1-\theta)^4 + 2\theta^3(1-\theta)^3 \\ +2\theta^4(1-\theta)^2 + 2\theta^5(1-\theta) + \theta^6\end{array}\right] \tag{4}$$

This function achieves a maximum at $\theta = 0$, with an LOD score of $\log_{10}(L(0)/L(0.5)) = 0.727$. Since parametric LOD scores are additive, we would require five or more pedigrees of this configuration to meet or exceed the standard for demonstrating linkage (a LOD of 3) (Morton, 1955).

4. Affected sibling pair linkage

We will next consider non-Mendelian disorders. Since there is substantially less power in a single pedigree, we will consider a set of nuclear pedigrees (two genotyped parents and two genotyped affected siblings) detailed in Table 1. We will use the Affected Sibling Pair (ASP) method of Risch (1990), as implemented by Kruglyak and Lander (1995) in MAPMAKER/SIBS. Let $\pi_j(i)$ denote the probability that sibling pair i shares j alleles identical-by-descent (IBD). Let (z_0, z_1, z_2) represent a specific hypothesis for average sibling pair sharing of IBD 0, IBD 1, and IBD 2; let (α_0, α_1, α_2) represent the random expectation under the null hypothesis of no linkage. Then, we compute the LOD score by summing over all sibling pairs:

$$\text{LOD} = \sum_i \log_{10}\left(\frac{z_0\pi_0(i) + z_1\pi_1(i) + z_2\pi_2(i)}{\alpha_0\pi_0(i) + \alpha_1\pi_1(i) + \alpha_2\pi_2(i)}\right) \tag{5}$$

For sibling pairs, the null hypothesis will be $(\alpha_0, \alpha_1, \alpha_2) = (1/4, 1/2, 1/4)$. In this example, IBD status is known with certainty at the locus in question for each affected sibling pair, so we can compute the MLEs for (z_0, z_1, z_2) through a simple proportion of pedigrees:

$$(z_0, z_1, z_2) = \left(\frac{18}{126}, \frac{60}{126}, \frac{48}{126}\right) = \left(\frac{1}{7}, \frac{10}{21}, \frac{8}{21}\right) \tag{6}$$

Table 1 IBD status at candidate locus for 126 quartets (2 parents, 2 affected offspring)

IBD status	0	1	2
Number of pedigrees	18	60	48

We do not require $z_1 = 0.5$; that is, we allow dominance deviation. These MLEs also lie within the "possible triangle" (Holmans, 1993): $z_1 \leq 0.5$ and $z_1 \geq 2z_0$. If the proportions resulted in MLEs outside of the possible triangle or dominance deviation was disallowed, then an EM algorithm could be used to find the parameters (Kruglyak and Lander, 1995). We then compute the LOD score:

$$\begin{aligned}
\text{LOD} &= \sum_i \log_{10}\left(\frac{z_0\pi_0(i) + z_1\pi_1(i) + z_2\pi_2(i)}{\alpha_0\pi_0(i) + \alpha_1\pi_1(i) + \alpha_2\pi_2(i)}\right) \\
&= \sum_i \log_{10}\left(\frac{1/7\pi_0(i) + 10/21\pi_1(i) + 8/21\pi_2(i)}{1/4\pi_0(i) + 1/2\pi_1(i) + 1/4\pi_2(i)}\right) \\
&= 18\log_{10}(4/7) + 60\log_{10}(20/21) + 48\log_{10}(32/21) \\
&= 3.135 \qquad (7)
\end{aligned}$$

5. Nonparametric linkage

Finally, we will consider Nonparametric Linkage (NPL) scores using Whittemore–Halpern statistics (Whittemore and Halpern, 1994; Kruglyak *et al*., 1996), implemented in GENEHUNTER. These statistics are based on a scoring function $S(v,\Phi)$, where Φ represents the phenotypic configuration of a particular pedigree and v is an inheritance vector – the inheritance pattern of segregation for a pedigree at a particular locus. Typically, the true inheritance pattern is unknown, so one computes the average over all possible inheritance vectors weighted by the probability of the vector:

$$\overline{S}(\Phi) = \sum_{w \in V} S(w, \Phi) P(v = w) \qquad (8)$$

There are several possible scoring functions. We will consider S_{pairs}, defined to be the number of pairs of alleles from distinct affected pedigree members that are IBD. We will consider only the case where the parents are unaffected so each pedigree will have one pair of affected individuals (namely, the sibling pair used in the previous example). Since segregation is unambiguous for the 126 nuclear families listed in Table 1, each affected sibling pair has a score of 0, 1, or 2. For each pedigree, mean and standard deviation of the scoring function (based on a uniform distribution of all possible inheritance vectors) are computed. For each pedigree in this example, the mean is 1 and the standard deviation is $1/\sqrt{2}$. The observed scores are then normalized on the basis of these values:

$$Z(i) = \frac{S(i) - \mu}{\sigma} = \begin{cases} -\sqrt{2}, & \text{if IBD} = 0 \\ 0, & \text{if IBD} = 1 \\ \sqrt{2}, & \text{if IBD} = 2 \end{cases} \qquad (9)$$

Finally, we sum the normalized score over all pedigrees, with a weight of $1/\sqrt{N}$, so that the final sum has mean 0 and variance 1 under the null:

$$Z = \sum_i \frac{1}{\sqrt{N}} Z(i) = 18\left(\frac{-\sqrt{2}}{\sqrt{126}}\right) + 60\left(\frac{0}{\sqrt{126}}\right) + 48\left(\frac{\sqrt{2}}{\sqrt{126}}\right) = 3.78 \quad (10)$$

Note that this is an observation from a normal distribution and not an LOD score as in the previous examples. For many likelihood ratio tests, twice the natural log of the likelihood ratio is asymptotically distributed as a chi-squared statistic, so we can compute an approximate equivalence since a normal squared is a chi-square with one degree of freedom:

$$\frac{Z^2}{2 \ln 10} = \frac{3.78^2}{4.6} \approx \text{LOD} = 3.10 \quad (11)$$

The ASP test for this example is slightly more significant, but this is only an approximation since the NPL is not based on maximization of a likelihood estimator.

Introductory Review

Genetics of complex diseases: lessons from type 2 diabetes

Leif Groop and Peter Almgren
Lund University, Malmö, Sweden

1. Introduction

A disease can be inherited or acquired or both. While cystic fibrosis is an example of an inherited disease, most infectious diseases are acquired. But susceptibility to an infectious disease can also be influenced by genetic factors. Heterozygous carriers of the mutation causing sickle-cell anemia are resistant against malaria (Miller *et al*., 1975). A 32-bp deletion in the gene encoding for the lymphoblastoid chemokine receptor (CCR5) was introduced in Europe during the plague by *Yersina pestis* in the fourteenth century (Stephens *et al*., 1998). Carriers of this deletion are today less susceptible to HIV infections.

Cystic fibrosis is caused by mutations in one gene, *CTFR*, and represents a monogenic disorder with early onset, usually from birth. The segregation of the disease follows a clear Mendelian recessive inheritance; in Europe is one out 2000 children affected. In contrast, a polygenic disease such as type 2 diabetes (T2D) is caused by "mild" variations in several genes and has a late onset. A polygenic disease is also referred to as complex because of its complex inheritance pattern. A complex disease often appears to be acquired; the development of obesity and T2D is triggered by environmental factors such as intake of dense caloric food and lack of exercise in genetically susceptible individuals.

2. Genetic risk

The *relative genetic risk (λs)* of an inherited disease is defined as the recurrence risk for a sibling of an affected person divided by the risk for the general population. The higher the λs, the easier is it to map the genetic cause of the disease. The λs value for cystic fibrosis is approximately 500, for type 1 diabetes (T1D) 15 and for T2D 3. It is, therefore, not surprising that cystic fibrosis was the first inherited disease to be mapped by linkage analysis (Kerem *et al*., 1989), whereas success for T2D has been limited (Florez *et al*., 2003).

The relative genetic risk should not be mixed by the *population attributable risk (PAR)*. This is important from a public health perspective, but does not tell anything

about the individual risk. It describes the fraction of a disease, which would be eliminated if the genetic risk factor were removed from the population. PAR is high in monogenic rare disorders such as cystic fibrosis (around 50) but low for rare alleles in complex diseases. If the disease-associated allele is common, PAR increases. This is illustrated by the role of the Apo $\varepsilon 4$ allele in the Alzheimer's disease. The PAR for Apo $\varepsilon 4$ in Alzheimer's disease is 0.2 because of the high frequency of the Apo $\varepsilon 4$ allele in the population (16%).

3. Genetic variability

Mapping of an inherited disease requires the identification of the genetic variability contributing to the disease. Such variability is often a change in a single nucleotide in the genome, a single-nucleotide polymorphism (SNP). There are about 10 million SNPs in the human 3 billion bp genome, which means one SNP at about 300 bp intervals. SNPs in coding sequences (exons) are seen at 1250 bp intervals. Microsatellites are short tandem repeats of nucleotide sequences (e.g., CA) found at about 5000 bp intervals. Whereas SNPs are frequently biallelic, microsatellites have multiple alleles and are thus much more polymorphic than SNPs. Several public databases provide information on SNPs (e.g., **www.ncbi.nlm.nig.gov/**SNP.

A SNP can either be the cause of the disease (causative SNP) or it can be a marker of the disease. This occurs when the disease susceptibility allele and the marker allele are so close to each other that they are inherited together, a situation called *linkage disequilibrium (LD or allelic association).* Such a combination of tightly linked alleles on a discrete chromosome is called a haplotype. While this region is characterized by little or no recombination (haplotype block), regions with high recombination rate usually separate haplotype blocks. An international effort to create a genome-wide map of LD and haplotype blocks is called the HapMap project (**http://www.hapmap.org/groups.html**). The hope is that by knowing the haplotype block structure of the genome, one would only need to genotype a few representative SNPs for the haplotype block (tag SNPs) rather than all SNPs.

4. Mapping genetic variability

The ultimate goal of mapping genetic variability is to identify the mutation causing a monogenic disease or the SNPs increasing susceptibility to a polygenic disease.

5. Linkage

The traditional way of mapping a disease gene has been to search for linkage between a chromosomal region and a disease by genotyping a large number (about 400–500) of polymorphic markers (microsatellites) in affected family members. If the affected family members would share an allele more often than expected by nonrandom Mendelian inheritance, there is evidence of excess allele sharing.

Ideally, such a genome-wide scan would be carried out in large pedigrees where mode of inheritance and penetrance is known. Since these parameters are not known and parents are rarely available in a complex disease with late onset, most genome-wide scans are performed in affected siblings with no assumptions of mode of inheritance and penetrance (nonparametric linkage).

The probability test of linkage is called the *LOD score* (logarithm of odds). Two loci are considered linked when the probability of linkage as opposed to the probability against linkage is equal to or greater than the ratio of 1000/1. An LOD score of 3 corresponds to an odds ratio of 1000/1 ($p < 10^{-4}$). In a study of affected sib pairs, a nonparametric linkage (nonparametric linkage score (NPL)) score is presented. Although this threshold was developed for monogenic disorders with complete information of genotype and phenotype, the situation in mapping complex disorders is much more complex. Lander and Kruglyak (1995) have proposed that the LOD threshold for *significant genome-wide linkage* should be raised to 3.6 ($p < 2 \times 10^{-5}$), while that for *suggestive linkage* (would occur one time at random in a genome-wide scan) can be set at 2.2 ($p < 7 \times 2^{-4}$). In addition, they suggest to report all nominal p-values < 0.05 without any claim for linkage. In reality, these thresholds differ from scan to scan depending upon information content. Therefore, these thresholds should be simulated using the existing data set before any claims of linkage can be made.

Accurate definition of the phenotype is a prerequisite for success but this may not always be easy and dichotomizing variables may result in loss of power. One alternative is, therefore, to search linkage to a quantitative trait, for example, blood glucose, blood pressure body mass index instead of diabetes, hypertension, and obesity.

Linkage in complex diseases will only identify relatively large chromosomal regions (often >20 cM) with often more than 100 genes. Fine mapping with additional markers can narrow the region further but at the end the causative SNP or a SNP in LD with the causative SNP has to be identified by an association study. Several approaches have been described to estimate whether an observed association can account for linkage (Li *et al*., 2004). Without the functional support, it is not always possible to know whether linkage and association represent the genetic cause of the disease. This can for many complex disorders require a series of in vitro and in vivo studies.

6. Calpain 10 and type 2 diabetes

In the first successful genome-wide scan of a complex disease such as T2D, Graeme Bell and coworkers reported in 1996 that significant linkage (LOD 4.1; $p < 10^{-4}$) of T2D diabetes to a locus on chromosome 2q37 (Hanis *et al*., 1996). Still, this region was quite large (12 cM) encompassing a large number of putative genes. A reexamination of the data suggested an interaction (*epistasis*) with another locus on chromosome 15 (LOD 1.5). This enabled the researchers to narrow the region down to 7 cM. Luckily, the 7 cM genetic map only represented 1.7 Megabases of physical DNA. To clone the underlying gene, they genotyped a number of SNPs in this interval and identified a three-marker haplotype, which was associated with

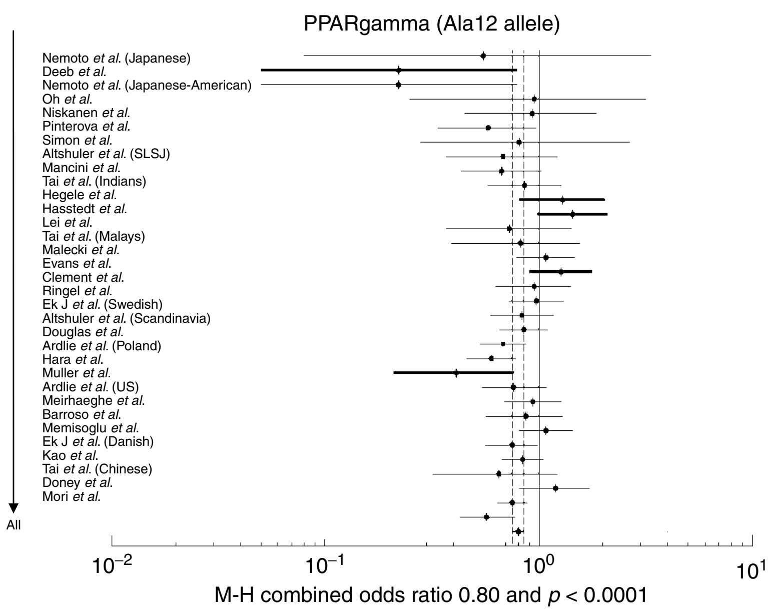
T2D. It turned out that three intronic SNPs in the gene encoding for calpain 10 (*CAPN10*) could explain most of the linkage (Horikawa *et al*., 2000). Calpain 10, a cystein protease with largely unknown functions in glucose metabolism, was no obvious candidate gene for T2D. Despite a number of subsequent negative studies, several meta-analyses have shown consistent association of CAPN10 with T2D (Parikh and Groop, 2004). Carriers of the risk alleles are associated with decreased expression of the gene in skeletal muscle and insulin resistance. How this translates into increased risk of T2D is not known and will require functional studies.

7. Gene expression

Since genes are transcribed to RNA and RNA is translated into proteins and defects in proteins cause disease, the ultimate goal would be to carry out a random search of expressed proteins in target tissues. This may not yet be feasible but the study of transcript profiles is. This approach has been successful in defining prognosis of cancers but for complex diseases affecting many target tissues it may not be that simple. Also, defining what is differentially expressed among >20 000 gene transcripts on a chip is a statistical challenge. Despite these problems, analysis of gene expression in skeletal muscle of patients with T2D and prediabetic individuals has provided new insights into the pathogenesis of the disease. It, however, required analysis of coordinated gene expression in metabolic pathways rather than of individual genes. Genes regulating oxidative phosphorylation in mitochondria showed a 20% coordinated downregulation in muscle from prediabetic and diabetic individuals (Mootha *et al*., 2003; Patti *et al*., 2003). Furthermore, a similar down regulation of the gene encoding for a master regulator of oxidative phosphorylation, the PPARγ coactivator, PGC-1α was observed. These findings suggest that impaired mitochondrial function and impaired oxidation of fat may predispose to T2D through a "thrifty gene" mechanism (see below).

8. Association studies

If there is a prior strong candidate gene for the disease, the best approach is to search for association between an allelic variant of the gene and the disease. This can either be a case control or nested cohort study. In a case–control study, the inclusion criteria for the cases are predefined, and thereafter, matched individual controls are searched representing the same ethnic group as the cases. In a cohort study, affected and unaffected groups are matched. Ideally, cohorts should be population based and older than cases to exclude the possibility that they still will develop the disease. The question of matching is crucial for the results, matching for a parameter influenced by the genetic variant (e.g., BMI) might influence its effect on a disease such as T2D. If cases and controls are not drawn from the same ethnic group, a spurious association can be detected due to ethnic stratification.



One way to circumvent this problem is to perform family-based association studies. Excess transmission of the disease-associated allele from heterozygous

parents to the affected offspring would indicate association in the face of linkage. This transmission disequilibrium test (TDT) represents the most unbiased association study approach but suffers from low power as only transmissions from heterozygous parents are informative. The prerequisite of DNA from parents usually enrich for individuals with an earlier onset of the disease.

Even screening only one gene for SNPs can represent a huge and expensive undertaking. The PPARγ gene on the short arm of chromosome 3 spans 83 000 nucleotides with 231 SNPs in public databases.

The gene encodes for a nuclear receptor, which is predominantly expressed in adipose tissue where it regulates transcription of genes involved in adipogenesis.

In the 5′ untranslated end of the gene is an extra exon B that contains a SNP changing a proline in position 12 of the protein to alanine. The rare Ala allele is seen in about 15% of Europeans and was in an initial study associated with increased transcriptional activity, increased insulin sensitivity, and protection against T2D (Deeb *et al*., 1998). A number of subsequent studies could not replicate the initial finding. However, using the TDT approach we could show excess transmission of the Pro allele to the affected offspring (Altshuler *et al*., 2000). A meta-analysis combining the results from all published studies showed a highly significant association with T2D ($p < 2 \times 10^{-10}$) (Figure 1). The individual risk reduction conferred by the Ala allele is only 15% but since the risk allele Pro is so common, it translates into a population attributable risk of 25%. There is also a strong interaction

Meta-analysis of the association between the Ala12 allele in the PPARγ gene and type 2 diabetes without Deeb *et al*., Hegele *et al*., Hasstedt *et al*., Evans *et al*. and Hara *et al*. studies (thick lines) to obtain homogeneity by Mantel–Haenszel Test of homogeneity.

Figure 1 A meta-analysis demonstrating the strong risk of the Pro12Ala polymorphism in the PPARγ2 gene and type 2 diabetes

with nutritional factors and the protective effect of the Ala allele is enhanced with a high intake of unsaturated free fatty acids (Luan *et al*., 2001). In fact, free fatty acids have been proposed as natural ligands for PPARγ.

It is still debated whether common or rare variants are the cause of common complex diseases. The common variant-common disease hypothesis assumes that relatively ancient common variants increase susceptibility to common diseases such as obesity, hypertension, T2D, and so on. These variants would be enriched in the population as they have been associated with survival advantage during the evolution, so-called thrifty genes (Neel, 1962). Storage of surplus energy during periods of famine may have been beneficial for survival, while in the Westernized society we rather need genetic variants which would waste energy.

9. Why is it difficult to replicate a finding of an association with a complex disease?

The literature on the genetics of complex diseases has been enriched with papers not being able to replicate the initial findings. There are several reasons for this. There is a clear tendency that the first study reports the strongest association, as researchers and editors prefer strong positive findings ("winners curse"). False-positive findings are unfortunately common. In an analysis of 301 published studies covering 25 different reported associations, only half showed significant replication in a meta-analysis (Lohmueller *et al*., 2003). The most important reason is lack of power. The odds ratio for a complex disease is often below 1.5. The sample size is dependent not only upon the odds ratio but also on the frequency of the at-risk genetic variant. For an odds ratio of 1.8 and a frequency of the at-risk allele of 25%, at least 1000 cases and controls are required (Figure 2).

10. Why do not linkage studies detect all associations?

Despite initial linkage, it has often been difficult to identify the underlying genetic variation. This is particularly difficult if the disease-causing allele has a high frequency in the population. If too many individuals will be homozygous for the disease allele, in which case one will not observe linkage between the disease allele and an allele at a nearby locus, because either of the homologous chromosomes can be observed as transmitted to an affected offspring. This was the case for the Pro12Ala polymorphism in the PPARγ gene. No linkage has been observed between T2D and the region for PPARγ on chromosome 3p, since the Pro allele will typically be transmitted from both parents. A simulation indicated that 3 million sib pairs would be required to detect such a linkage (Altshuler *et al*., 2000).

11. Future directions

The rapid improvement in high-throughput technology for SNP genotyping and decreasing costs per genotype (in 10 years the cost has decreased by a factor

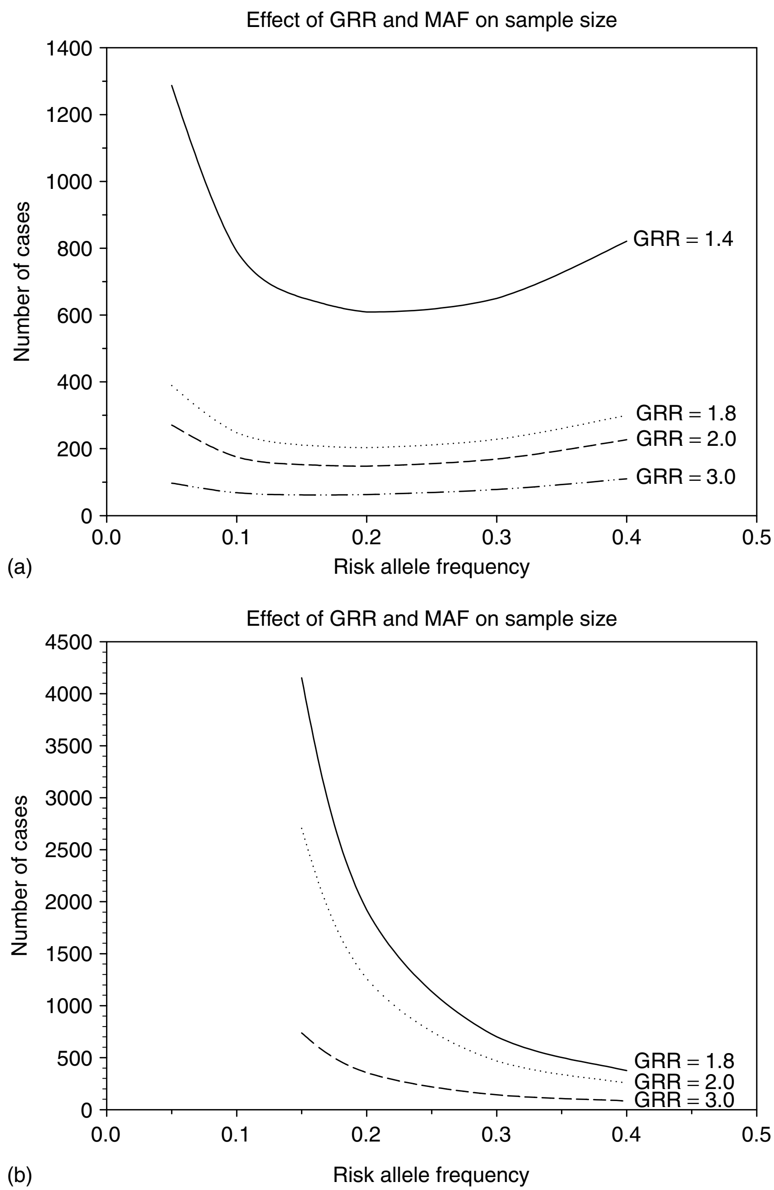


Figure 2 Number of cases and controls required for association studies are dependent upon the estimated odds ratio and the frequency of the at-risk allele. (a) Dominant model; (b) recessive model

of 10) open new possibilities for both linkage and association studies. The use of DNA chips containing >11 000 SNPs for genome-wide scans is estimated to be much more powerful than previously used 450 microsatellites (Middleton *et al*., 2004).

Such high-density DNA chips may be useful for detecting rare genes with a strong effect in large pedigrees, but for the detection of the genetic variation of complex diseases, association studies are needed. In the near future, it will be possible to perform genome-wide association studies using SNPs. If the common variant–common disease hypothesis holds, it may be possible to obtain an atlas of disease-associated genetic variants using approximately 500 000–1 000 000 SNPs. This will not be a cheap undertaking and it is obvious that while the tools are there, money is still the limiting factor for dissecting the genetics of complex diseases.

Introductory Review

Importance of complex traits

Joseph H. Lee
Columbia University, New York, NY, US

1. What is a complex trait?

Complex traits refer to traits that do not follow simple Mendelian inheritance. These include most common chronic diseases (e.g., Alzheimer's dementia, coronary heart diseases, obesity), infectious diseases (e.g., hepatitis, malaria), and common physiological traits (e.g., blood pressure, obesity). These common diseases or traits contribute much to the public health burden in both the developed and the developing countries. For example, the three most common types of diseases – cancer, cardiovascular diseases, and neuropsychiatric disorders – account for approximately 56 and 25% of the years of life lost to premature death and years lived with a disability in the developed countries and the developing countries, respectively (WHO, 1999). To develop effective therapeutic and preventive measures, it is desirable to identify the underlying genetic and environmental factors to understand the biology of these diseases. However, identification of the underlying causes is difficult for these traits because there are multiple genetic or environmental factors, and each individual factor is likely to contribute only little toward the disease or the trait. Further, these factors can interact to produce different effects. A number of different approaches have been applied to reduce the complexity and to understand the underlying components, but challenges still remain.

2. Genetic architecture of complex traits

Most traits are caused by a network of genetic and environmental risk factors (Figure 1). Obviously it is difficult to characterize any causal relations in a one-to-one manner, since a single factor among a collection of interrelated factors is likely to explain only a small proportion of variation in phenotype. Moreover, when the distribution of these cofactors differs in different samples, the observed association between any one potential putative factor and the trait is likely to vary, leading to inconsistent observations across studies. For example, in one population, Gene 1 may be the predominant form leading to the disease; while in another population, Gene 3 may be most prevalent, leading to a conclusion of "nonreplication" of the

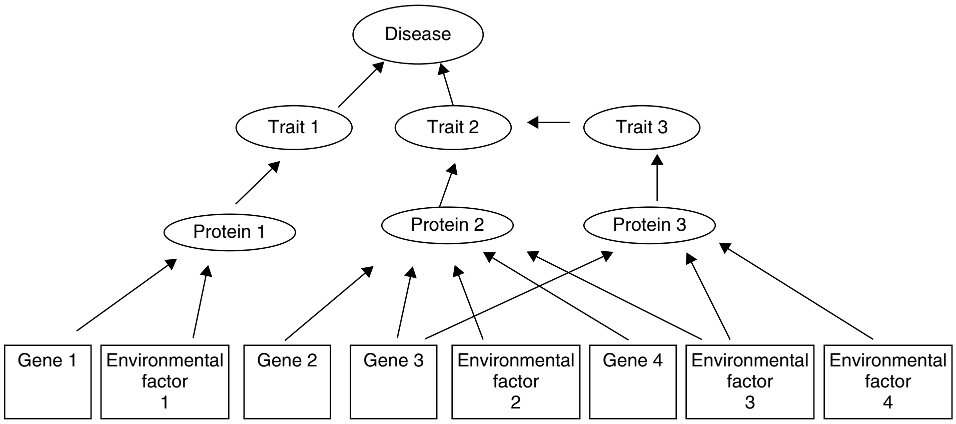

Figure 1 This simplified figure shows how genetic and environmental factors contribute to causal pathways toward a common disease

first association. Thus, depending on the population sampling, the observed support for a causal relation with a genetic factor can vary.

In complex disorders, genes not only confer small to modest effects on the disease, but are likely to contribute to variable expression via many different means, as in earlier age at onset, varying levels of severity, or some other means. Moreover, mechanisms by which these genes influence the trait may deviate from our traditional understanding of genetic inheritance. Imprinting affects the phenotypic expression of a genetic variant by its parent of origin, and this phenomenon has been reported in some cancers and neuropsychiatric diseases (Bjornsson *et al.*, 2004). Others have reported that gene duplications and deletions may alter normal physiological variations and eventually the risk of cancers, depending on the copy number polymorphism (Buckland, 2003). Some reports have shown that variants in mitochondrial DNA contribute a wide range of phenotypes, including aging, neurological disorders, and diabetes (Wallace, 2005). These illustrate that determination of genetic mechanism, even after the gene has been identified, can be difficult. Moreover, some environmental factors can have major contributions, while those of others may be minor. Because some behaviors (e.g., smoking, diet, academic achievement) run in families and can mimic genetic transmission, disentangling the multitude of etiologic factors requires a careful study design and multiple approaches.

3. Different study designs for different purposes

To understand the nature of the complex trait, researchers have used a number of different study designs to delve into the network of causation. They have attempted to determine evidence of genetic effect, identify the gene, measure the effect size of the gene, and then assess its functions. To assess the role of genetic factors directly or indirectly, researchers have used twin studies, adoption studies, genetic isolate studies, and family studies. Detailed discussion of the strengths and weaknesses

of these study designs are discussed elsewhere (Rao and Province, 2001; Strachan and Read, 1999; Terwilliger and Goring, 2000). It is hotly debated as to what an optimal study for complex traits would be (Botstein and Risch, 2003; Hirschhorn and Daly, 2005; Weiss and Terwilliger, 2000; Wright *et al*., 1999). In the end, each disease or trait will require a somewhat different study design, depending on the hypothesis to be tested and the available study samples. Fundamentally, to identify genes, it is generally desirable to simplify the complex relations among causal factors, and this is best achieved in a family study design. This approach can be further simplified by examining genetically isolated populations. On the other hand, to characterize population parameters (e.g., a gene's effect size and its impact in the population), it is desirable to include all the factors that are believed to be significant contributors. For this purpose, a population-based epidemiologic study design is more suitable.

Traditionally, large extended families with multiple affected individuals were used to identify genes. It is reasoned that if a gene causes a disease, it is likely that the disease will "run" in that family, and will lead to many affected family members, who share the risk alleles from some common ancestor. Thus, the gene can be localized to some chromosomal region by linkage analysis. Linkage analysis is based on the observation that chromosomal loci that are physically close will tend to be coinherited more often than will two random loci in the genome. A disease-causing or a disease-influencing variant will cosegregate with nearby genetic markers. Thus, by identifying genetic markers that are shared by affected individuals in a given family, it will be possible to identify chromosomal regions that may harbor the disease gene. Using this principle, researchers have searched the human genome to identify many causative genes, mainly for Mendelian disorders (McKusick, 1998). In general, the ascertainment using large families increases the predictive power of phenotype for the underlying genotypes. Because a limited number of large families are examined and the environment within the family is more similar than in random samples, this approach reduces the number of genetic variants and environmental risk factors, thereby reducing the complexity. Examples of genes for complex traits identified to date using large families include Breast Cancer Gene 1 and 2 (*BRCA1*, *2*) (Hall *et al*., 1990; Miki *et al*., 1994; Tavtigian *et al*., 1996; Wooster *et al*., 1995) for breast cancer, and presenilin 1 and 2 (*PS1*, *2*) (Levy-Lahad and Bird, 1996; Rogaev *et al*., 1995; Sherrington *et al*., 1995) and apolipoprotein E (*APOE*) (Strittmatter *et al*., 1993) for Alzheimer's disease (AD).

Other researchers have argued against using large families because such large families with multiple affected individuals are difficult to find and the identified genes tend to be rare so that they explain only a small and unique proportion of the disease (i.e., the "familial" variant of a given common disorder). As a result, many opted to recruit a greater number of smaller families, such as affected sibling pairs, trios (parents and affected child), or even cases and controls. However, these approaches have had limited success. As a large number of sibling pairs, trios, or cases and controls are used, the number of genetic variants in affected individuals as well as the number of environmental risk factors will increase, so each risk factor will explain proportionately less of the phenotypic variance in the samples studied.

Recently, many investigators have combined existing large population-based studies with high-throughput and high-resolution genotyping technologies to search

their way through the genome in genome-wide association studies. This approach uses the principle that the allelic association can be made directly with single-nucleotide polymorphisms (SNPs) that cause an amino acid change (Botstein and Risch, 2003) or with SNPs that are close to the true disease-causing variant (Hinds *et al*., 2005; Maraganore *et al*., 2005). Several issues need to be considered when evaluating allelic associations. First, population stratification can lead to false-positive findings. This happens when cases are recruited from an ancestry that is different from that of the controls, thereby leading to different allele frequencies between the two groups, independent of the disease status. Consequently, the allele frequency difference between ethnic groups will be falsely attributed to the allele frequency difference between cases and controls. This problem will need to be addressed using genomic control methods (Devlin *et al*., 2004). Second, because of the nature of linkage disequilibrium (see Article 000, **Impact of Linkage Disequilibrium on Multipoint Linkage Analysis**, Volume 0), allelic association requires a great many more markers compared to linkage analysis. For example, because of multiple markers tested, a SNP needs to achieve a nominal p value of 5×10^{-7} to be comparable to the Bonferroni corrected p value of 0.05, when a "100K SNP chip" (i.e., 100 000 markers) is used for the genotyping. This is only for one phenotype. To circumvent this problem, some have advocated a two-stage design in which one dataset is used to screen for candidate SNPs associated with the disease, and then the finding confirmed or refuted in another dataset (van den Oord and Sullivan, 2003). Moreover, even when 100 000 SNPs are tested, they cover $<50\%$ of the common variants (Hirschhorn and Daly, 2005); therefore, there is a risk of overlooking a significant number of common variants that may contribute to the disease. Third, perhaps the most significant difficulty lies in allelic heterogeneity, which cannot be overcome by statistical means. To identify susceptibility genes using the allelic association approach, it is necessary to identify not only the correct genetic marker but also the correct allele. For example, using large extended pedigrees, it was found that PS1 mutations cause familial early onset Alzheimer's disease (EOAD). However, even for this 'less complex' subset of Alzheimer's disease, researchers have identified 155 allelic variants from 315 families (**http://www.molgen.ua.ac.be/ADMutations/**) thus far, and the number will only increase. Thus, if a SNP chip is used for diagnostic purpose, the results from such tests may still be less than conclusive. Lastly, these susceptibility alleles confer only small effects; thus, the effect size will vary considerably depending on the set of genetic and environmental risk factors present.

Despite these difficulties, some have reported successes. Klein and colleagues examined 116 204 SNPs using 96 cases and 50 controls (Klein *et al*., 2005). The authors identified that a common variant in an intron of complement factor *H* gene was strongly associated with age-related macular degeneration. However, it is of interest to note that this locus had been reported by linkage analysis. Herbert and colleagues (2006) reported a common allele near the *INSIG2* gene that is associated with adult and childhood obesity. For this purpose, the authors examined multiple datasets, including families, trios, and cases–controls, and found the association to be significant in four of five datasets. However, to minimize the number of statistical tests, the authors used a two-stage approach in which they screened 86 604 SNPs in parents, and then tested the top 10 SNPs with the greatest power

to detect allelic association in their offspring. They identified one SNP from this analysis and confirmed it in four different datasets. Although these two studies report positive findings based on a genome-wide association approach, it remains to be seen whether this approach can be fruitful even after "low hanging fruits" have been picked.

Estimation of genetic parameters, once a susceptibility gene has been identified, requires large randomly selected samples. This avoids the ascertainment bias that lead to overestimation of gene parameters (e.g., allele frequencies, attributable risk) arising from the extreme samples that identified the gene. For example, *BRCA1* identified from the large pedigrees with multiple breast cancer cases was thought to be highly prevalence and penetrant. In one study, 84% of the families with four or more cases that had onset prior to 60 years of age were associated with either *BRCA1* or *BRCA2* mutations (Thompson and Easton, 2004). In the population-based studies of randomly selected population samples, however, the prevalence of mutations in this gene was $<5\%$, highlighting the strong influence of ascertainment on genetic parameters.

4. Endophenotype

As a means to simplify the complexity, biologically relevant endophenotypes can help us to understand the biology better. A genetic variant can have a cascading effect on protein structure, protein synthesis, and gene expression levels, while environmental factors can modulate the effect of the genetic variant each step along the way. Common diseases are far removed from direct actions of the underlying genetic and environmental factors (Figure 1). To identify the genetic or environmental risk factors, it makes sense to study intermediate phenotypes that are closely associated with metabolism, physiology, structural integrity, and related traits, which are themselves risk factors for the disease. These traits tend to be continuous (rather than affected vs. unaffected), so that they explain normal variations in the population. For example, endophenotypes can include cholesterol levels for coronary heart disease and amyloid β level and brain structure for AD. Essentially, the use of endophenotypes strengthens genotype–phenotype relations, and increases the predictive power of phenotypes for genotype. Consequently, it reduces the likelihood of falsely concluding an effect of phenocopy.

Currently many studies use endophenotypes instead of clinical endpoints to better understand complex traits. For example, using amyloid β protein level as the phenotype, Ertekin-Taner *et al*. (2000) localized a susceptibility gene for AD to 10q, which was confirmed in two independent studies (Bertram *et al*., 2000; Myers *et al*., 2000) that used AD as the phenotype. Others have used endophenotypes – such as P50 and P300 event-related potential wave measures for schizophrenia (Blackwood *et al*., 2001; Freedman *et al*., 1997) and blood coagulation for the risk of thromboembolic disease (Souto *et al*., 2003)–to localize the susceptibility locus for the clinical endpoints. In addition, these endophenotypes can be used to disentangle the complexity of the clinical endophenotype. Lee *et al*. (2006) showed, using memory scores as the phenotypes, that one candidate gene was more likely to contribute to AD via memory impairment, while another was more

likely to contribute to variation in memory in healthy elderly. From the practical standpoint, the several advantages of studying endophenotypes are as follows: (1) ascertainment is simpler; (2) greater information can be obtained as everyone has measurable values as part of normal human variation; and (3) there is efficiency as multiple quasi-independent quantitative traits (e.g., body mass index, lipid profile, intraocular pressure, bone density, vision, etc.) can be obtained from a single study.

In sum, complex traits present a major challenge for biomedical scientists, as current approaches have yielded limited success. No single approach can provide the best answer to our understanding of complex traits. It is necessary to choose an optimal study design for the hypothesis of interest and apply multiple integrated approaches.

Specialist Review

Concept of complex trait genetics

Kenneth M. Weiss and Anne V. Buchanan
Pennsylvania State University, University Park, PA, USA

1. Complex traits and common disease

In genetics, the term "complex" is not standardized but usually refers to traits for which there is no single cause with uniformly high predictive power. Complex traits are thought to involve both multiple genes and environmental risk factors, as well as interaction between a gene and other genes and/or the environment. However, it has generally not been possible to enumerate an exhaustive set of associated genes or environmental risk factors for such traits. This is in part because the relationship between genotype and phenotype is in most cases not one to one, though there may be some instances, usually rare, that follow Mendelian patterns of inheritance or that seem to have a single major cause. In fact, an enumerable, exhaustive set of causes may not even exist because the factors are dynamic, changing, or variable over time or space within and among populations.

Complex diseases are currently the focus of much attention in human genetics and epidemiology because they are the most common causes of morbidity and mortality in industrialized nations. In addition to efforts to understand causation, they are considered to be potentially good targets for pharmacogenomic intervention. Complex diseases are a mixed set of traits, however; some, including cardiovascular diseases, hypertension, diabetes, cancers, asthma and other pulmonary diseases, allergies, psychiatric disorders, and Alzheimer's disease, are common chronic complex diseases in the fullest sense defined above. Others, such as Hirschsprung disease (Gabriel *et al*., 2002) or Bardet–Biedl syndrome (Eichers *et al*., 2004), are rare and seem to be due to several genes, while still others, such as autoimmune disorders, are relatively rare but apparently involve major contributions from both genes and environment. Even some traits with the simplest genetic etiology involve many of the same elements of complexity (Scriver and Waters, 1999).

Complex diseases also differ in age at onset; some, such as Alzheimer's or coronary heart disease, develop only after decades of healthy life, while others are diseases of childhood, for example, allergic asthma and many psychiatric disorders. And the prevalence of many of them has risen sharply in recent decades (NIDDM, autism, and asthma), or even fallen dramatically (cardiovascular disease in North Karelia, Finland, for example, where heart disease mortality rates were once the highest in the world but which have fallen by 75% in the last several decades (Neroth, 2004)). These changes clearly show the involvement of environmental

factors. However, the prevalence of other complex traits has remained fairly stable over time (e.g., some of the psychiatric disorders), and may be similar in very different populations.

Many complex traits, particularly those that arise at older ages, are best viewed not as biological entities per se, but as the tail ends (extremes) of the distribution of normal variation. In such cases, risk can be described statistically in terms of the deviation of an individual's underlying risk from the population mean. Cholesterol, weight, blood pressure, and glucose tolerance are such factors, for which everyone in the population has a value, but for which the probability of associated pathology increases when these measures fall in the upper tail of the distribution. Many of these traits are intermediate variables in a pathway from normal to disease, as illustrated in Figure 1(a). In fact, conditions such as "high" blood pressure or glucose levels are often defined not by their own pathological symptoms, but by an arbitrarily decided level of statistical risk for some future outcome (stroke, diabetes), based on population-level correlations. This is important to keep in mind as we try to understand the biological nature of complex traits.

There clearly is not a one-size-fits-all explanation for this diversity of traits. An example that illustrates some of these points, and shows the difficulty of attributing causation, is allergic asthma (for a more in depth discussion, *see* Article 61, **Allergy and asthma**, Volume 2). Asthma has become a very common disease in industrialized countries, most often arises early in childhood, and may involve a critical period during development, perhaps of the immune system, during which exposure to an environmental insult is the trigger. The condition aggregates in families (that is, risk is higher for children with affected sibs than for random children in the population), but does not segregate in a Mendelian way as if caused by a single gene. Recent reports of genes "for" asthma (*ADAM33*, or different interleukin genes, see, for example Wills-Karp and Ewart, 2004) have been equivocal, replicated by some studies but not by others.

Noninsulin dependent diabetes mellitus (NIDDM), or type II diabetes, is another complex disease whose epidemiology suggests a genetic component, although prevalence rises significantly in all populations that "westernize", that is, are exposed to an overabundance of calories, with reduced levels of physical activity (Stern *et al*., 1991; Trowell and Burkitt, 1981). Unlike asthma, NIDDM usually develops gradually at later ages, although age at onset has been falling in high-risk populations and now even children are developing what used to be an adult onset disease. The history of the disease in the last century suggests the involvement of exposure to some environmental trigger, perhaps in childhood, or even in utero. The factor(s) seem likely to involve diet and exercise in some way. Comparative epidemiology of this disease in different populations suggests the possibility of a relatively simple genetic risk, at least in some populations, but even so, the rise in prevalence with lifestyle changes strongly implicates environmental risk factors; NIDDM may be one of the most significant examples of a common complex disease due to gene-environment interaction. Numerous searches for diabetes genes in different populations, most notably Native American groups in which NIDDM prevalence is very high, have mainly yielded suggestive or even contradictory results, or genes of only minor contributory effect. Few genes are known in which

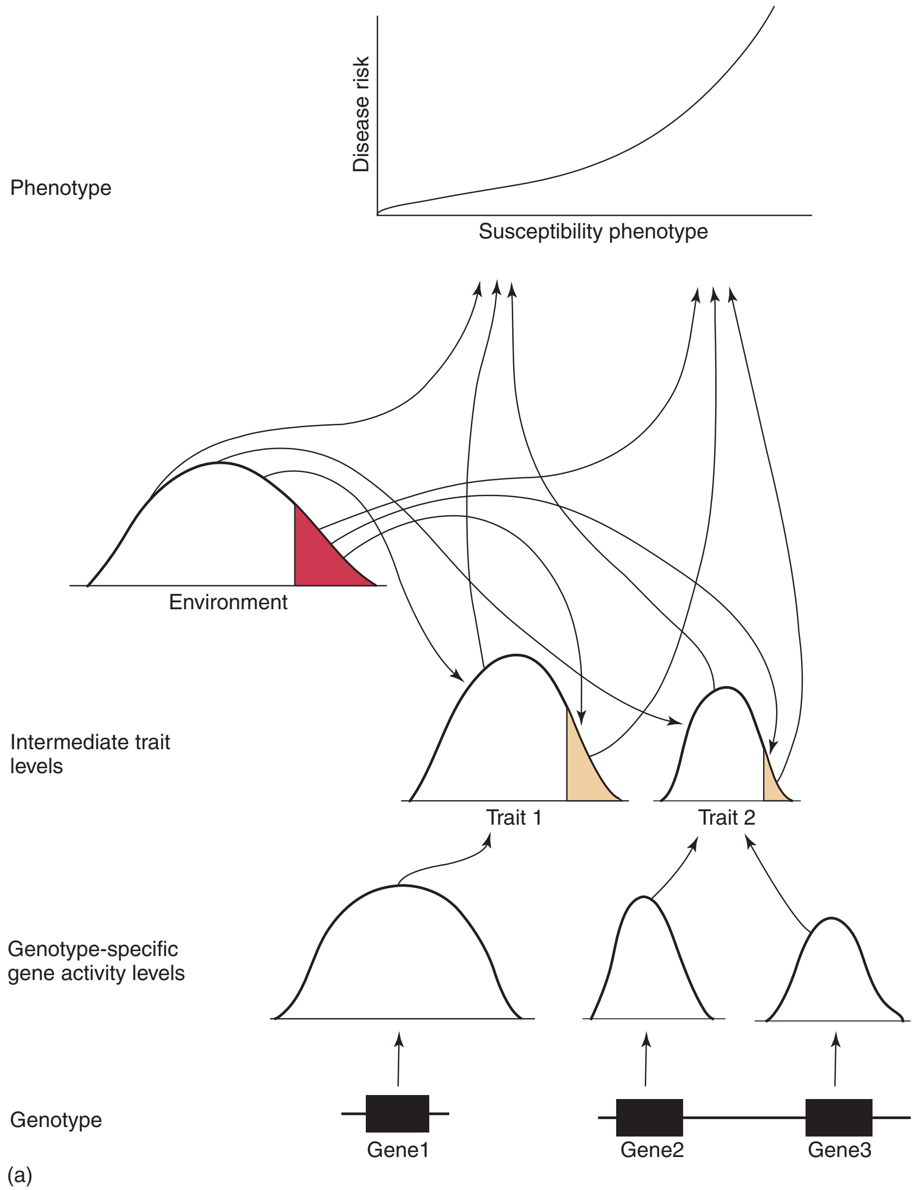

Figure 1 (a) Pathway from genotype to disease phenotype, showing genes 1, 2, and 3 yielding distributions of allele frequencies, which, singly or with other genes and environmental factors, lead to the distribution of traits (cholesterol or HDL levels are possible examples) that, at their extremes and in interaction with environmental risk factors, can increase risk of disease; (b) Hourglass figure showing that many genotypes may produce intermediate traits that can be risk factors for disease, alone, with other genes, and/or environmental risk factors

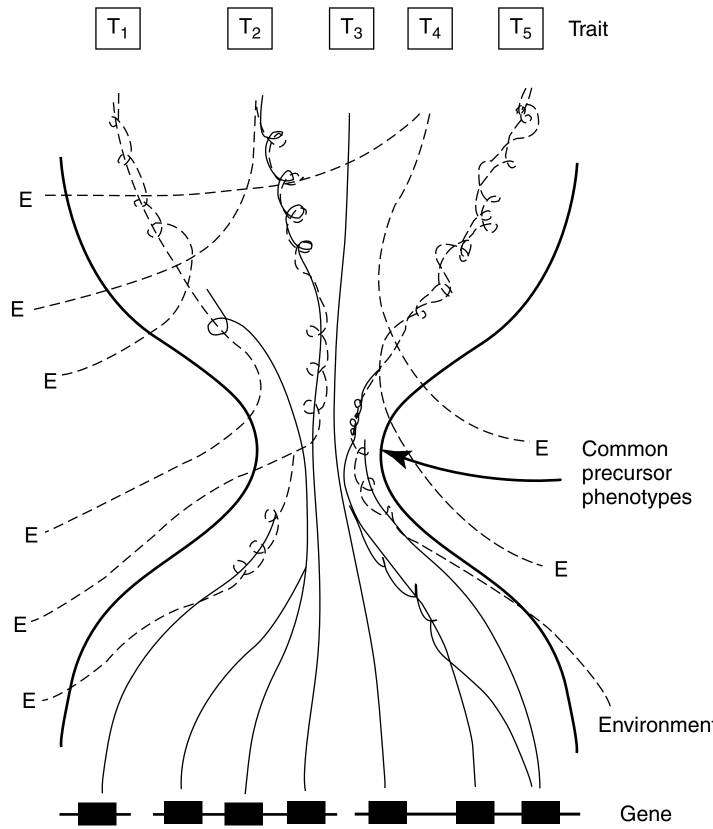

Figure 1 (*continued*)

mutations confer very elevated risk, and these only account for a small fraction of all cases.

Psychiatric disorders are usually considered genetic diseases when there is evidence that cases aggregate in families, at least to some extent (*see* Article 64, **Genetics of cognitive disorders**, Volume 2), and when the biochemistry seems to be suggestive of genetic involvement, but as of yet, none has been substantially explained in genetic terms. Autism has an early age at onset, and siblings of affected children have a higher risk than the general population, suggesting a genetic component, but the phenotype varies considerably, even within affected families, and this has made it particularly difficult to study. Again, incidence has been rising rapidly in the industrialized world, and changing diagnostic criteria, infectious or environmental agents such as preservatives used in childhood vaccines, as well as genes, have all been implicated, but the etiology is scarcely better understood now than when incidence began to rise more than a decade ago, and the search for genes involved has yielded some suggestive loci but little in the way of definitive results (Veenstra-VanderWeele and Cook, 2004).

2. Analytic issues

The above examples are biologically very different, but share the same general epidemiological features – clustering of risk in families that implicates genetic risk factors, and rapid rise in prevalence that suggests a role for environmental factors. The basic theoretical model for the *genetics* of such traits has been known since early in the twentieth century. Complex traits, even including quantitative traits such as blood pressure or stature, reflect the combined effects of alleles at many independently segregating "Mendelian" loci. Individuals inheriting different combinations of alleles at the loci can have a similar phenotype; that is, even under the simplest of circumstances, and only considering genes, there is a many-to-one relationship between genotype and phenotype. If only a modest number of loci contribute substantial effects, the trait is sometimes called *oligogenic*, whereas if a large number of loci contribute, the trait is called *polygenic*. Even most oligogenic traits have a polygenic "background", that is, many alleles of individually very small effect modifying the phenotype. Polygenic effects are so numerous and small that they are not individually identifiable in practice.

In any given population, most loci contain at most a small number of common alleles, and many rare ones (frequency $<1\%$ or even much less). In some instances or in some populations, rare alleles at some loci may have strong effect on the trait (high "penetrance"). These effects will manifest Mendelian segregation in families and the genes can be mapped by existing methods. Such genes are sometimes referred to as *Quantitative Trait Loci* (QTL). QTL alleles are usually individually rare so that any given family will be affected by only one of them, but the specific allele or locus will differ among families; this is known as *multiple unilocus* etiology.

Common alleles with strong effect can be mapped, just as rare ones can, although an allele that is very common essentially defines "normal" rather than disease. For this reason, there is typically a confounding of size or strength of effect of an allele and its frequency. Strong effects are usually rare, because strong effects usually mean far from normal. This leads to serious analytic challenges, especially if weaker effects are more responsive to environmental conditions, as seems likely.

Overall, the genetic contribution to a complex phenotype (P) can be viewed very schematically as the result of some mean or scaling value (μ) plus contributions from various risk factors: $P = \mu + Q + PG + SN$, where Q represents genetic variants with mappably strong effect (QTL), PG from polygenes, and statistical error or "noise" (SN) due to uncertainties of various sorts including measurement error (some models do not include a mean term). For more details on mapping strategies and methods (*see* Article 9, **Genome mapping overview**, Volume 3).

Another reason harmful alleles are generally rare is that they usually will be eliminated from the population by natural selection, so that harmful alleles in the population at any given time are typically on their way out. Alleles with major effect that are at more than very low frequency may have (or have had in the past) some balancing benefit that keeps them in the population. It is a matter of interest to understand what the selective factors may be, although selection cannot be relied upon to have simplified a complex trait. As examples routinely show, a variety of loci and alleles can respond to any given selective factor. The classic example is

the many alleles, differing in different parts of the world at the loci coding for the proteins in hemoglobin, that are associated with resistance to malaria. Malaria is a serious disease that will favor any alleles present in a given local area that provide resistance. Malaria is a strong selective agent, if an allele's effect is also strong. But alleles with small effect, or with effect only in association with others or with environmental factors – likely attributes of complex disease alleles – are less susceptible to selection. In particular, if a disease arises only at late ages, causal genotypes are likely beyond the reach of natural selection, which works only through differential reproduction.

For this reason, genes that contribute to complex diseases of late (postreproductive) onset probably have not been targets of natural selection (at least not in relation to the modern chronic disease in question), so their frequency distribution will generally be as described earlier, that is, the loci will have a small number of common, and many rare, alleles. At present, there are only a few reliable examples of common variants with substantial effect on common disease. This issue of how many we should expect to find is contentious, however, for two reasons. First, common alleles with small effect on risk are very difficult to find by the usual genetic mapping study designs. For example, a common low-penetrance allele will be present in many unaffected people, requiring large case-control studies to detect its excess presence in affecteds. Some case-only study designs have been developed that can be used under some circumstances to circumvent this problem, which is exacerbated even further when there is causal heterogeneity, as typifies complex traits. Secondly, small effects can be important to discover because, while perhaps only of minor effect on the risk to any individual carrier, if they are common enough they can have noticeable effect on the rates of disease in the population (*see* Article 59, **The common disease common variant concept**, Volume 2).

Genetic complexity can arise in another way that is invisible to natural selection – and to linkage or association mapping studies. During an organism's life, every mitosis produces somatic daughter cells that can carry *somatically* arising mutations that are then transmitted to those cells' somatic descendants. Individuals are somatic mosaics, and if enough descendant cells are affected, somatic mutation can lead to disease, but because the mutations are not in the germ line, such causation will be invisible to mapping studies that are based on parent–offspring transmission. Cancer is one major example of disease affected or caused by somatic mutation, but there may be many others.

Overall, the nature of genetic effects on complex traits can be summarized by an hourglass metaphor of causation (Figure 1b). Many genotypes in a population constitute a wide base of ultimate risk factors that, often in interaction with environmental factors, converge to the same proximate risk factor, which in turn may have diverging phenotype effects. For example, many diverse genotypes contribute to high circulating cholesterol or triglyceride levels, but high cholesterol levels can have divergent disease effects, such as hypertension, obesity, heart attack, stroke, and others. One can focus therapeutic measures on the narrow waist of the hourglass – elevated cholesterol – without concern for the *specific* genotype involved in each case. Thus, statin drugs inhibit cholesterol synthesis, helping control circulating cholesterol levels and reducing their pathologic consequences, but with no effect on the physiologic pathway that caused the elevated cholesterol.

3. Complex traits are due to interacting factors

The model as discussed so far only considers the genetic aspects of complex traits, but few traits, including few human diseases, are due to genetic factors alone – cholesterol levels, of course, are also affected by diet, and can be influenced by dietary changes – and the genetic factors themselves may not contribute additively, but interactively. An additive contribution by an allele is the same regardless of other alleles in the person's genotype. When there is *epistasis* (gene–gene interaction), the effect of an allele at one locus depends on the genotype at one or more other variants in the person's genome (at the same or some other locus). Epistatic interactions are represented symbolically by a product term, conventionally denoted *GxG*. The impact of epistasis on disease risk is debatable; most studies indicate that the majority of effects are additive, but for technical reasons, there has been much less effort made to date to search for epistatic effects, and other statistical approaches may be used to find them when they exist. The rules of genetic inheritance are basically clear, but there are no a priori rules on genetic *effects*.

Perhaps far more importantly, it seems clear that the prevalence of most complex traits is heavily affected by nongenetic factors usually referred to collectively as *environmental*. These can include the various effects of lifestyle, such as diet and physical activity levels, or exposure to toxins or radiation, or many other factors. The problematic success record of environmental epidemiology suggests that environmental risk factors with small or interactive effect are unknown or at least the details of their effects are not understood. Thus, "diet" contributes to many diseases, but it is rarely clear how the specific components, subcomponents, combinations, or exposure histories actually affect risk. This uncertainty is reflected in the oscillations in public health recommendations in regard to many nutrients (e.g., unsaturated vs. saturated fats), therapeutic exposures (diagnostic mammograms), drugs (e.g., hormone replacement), and many others.

Like gene–gene relationships, environmental exposures can interact or contribute additively and there is no single rule. More importantly, environments and genotypes clearly interact in major ways. This phenomenon is symbolized in genetic models as *GxE.* The clearest evidence is the rapid recent rise in prevalence of many complex diseases, such as the examples described earlier, that seem to have an elusive genetic component. With many environmental agents, many possible genotypes, and many exposure regimes, it is very difficult to evaluate most *GxE* interactions or to replicate findings among studies, even if environmental factors could be measured with sufficient accuracy, which is often not the case.

In the end, we can summarize the logic of complex causation as

$$P = \mu + G + PG + E + GxG + GxE + ExE + SN \tag{1}$$

Each single term symbolically represents what may be an aggregate of many individual terms (for example, *G* may represent additive effects of genotypes at several loci, and *E* may represent several measured environmental factors) that, when known, appear as individual terms in a real application. Risk of each variable is quantified by some form of *regression*, or dose-response parameter, for example,

$\beta x Smoking$, where *Smoking* is measured in cigarettes consumed per day and β is the effect on the phenotype per cigarette per day.

An important thing about such models is that they are *statistical* and based on the existing variation in the population. An epidemiological study is necessarily a *sample* of that variation, rather than a perfect representation – and the population may never exactly replicate its own genetic or environmental exposure history. The models are *parametric* in that, except for the modification of each person's risk by the other measured factors in the risk equation, the same dose effect, β, is assumed to apply no matter who is doing the smoking or how many cigarettes are smoked. This is an assumption about the nature of the causal world that is analytically tractable, but except for strong effects, not easy to confirm as an accurate representation. For example, an average dose effect may be the combination of a few people at very high risk from that dose and other people who are immune to it.

4. Why so many inconclusive findings?

The identification of genes associated with disease has largely been based on the point-causation worldview made possible by the discovery of Mendelian segregation of particulate risk factors: a person inherits a genotype as a point-source exposure, that is, at conception. Over the past half-century this model worked with increasing ease to find genes responsible for hundreds of diseases, best-known examples being cystic fibrosis, sickle-cell hemoglobin, phenylketonuria, and Huntington's disease. Although most cases of these diseases are due to effects of variation at a single locus, the more intensely studied even these diseases were, the more complex we learn that they are (see Table 1), involving many different mutations and other factors (Scriver and Waters, 1999; Weiss and Buchanan, 2003).

Epidemiology has a similar history of success with infectious disease and disease caused by environmental exposures, such as smoking or asbestos. The effect of the risk factor is strong. But, as with Mendelian reasoning in genetics, epidemiological reasoning that works so well for diseases with strong main-effect causation does not work as well when such causation does not pertain. Although there have been major advances in the detection of important genetic mutations for complex diseases, it generally has not yet been possible to break these traits down into enough reliable genetic causal elements to generate genetically-based interventions on a public health scale. Most cases remain unexplained. Similarly, it has generally not been possible to identify major environmental risk factors for chronic disease that would make behavioral or policy interventions an effective way to prevent these diseases. It is known that diet and exercise can prevent some heart disease or diabetes, but not always, and this is primarily because obesity and inactivity are intermediate factors in the pathway to disease. And although there is plenty of suggestive evidence, much of it contradictory, we do not yet know which environmental factors trigger most of these diseases, so that prevention is not yet an option.

The usual finding for complex human diseases is that most cases arise sporadically (without specific known cause), but that a few families segregate the disease in a monogenic Mendelian way. Genes associated with asthma, diabetes,

Table 1 Numbers of alleles at selected disease-related genes

Gene (trait)	Mutations
CFTR (cystic fibrosis)	1011
LDL receptor (heart disease)	793
BRCA1 (breast, ovarian cancer)	603
DMD (muscular dystrophy)	597
PAH (phenylketonuria)	447
BRCA2 (breast, ovarian cancer)	388
TP53 (colon, other cancers)	264[a]
Pax6 (eye problems)	189
GBA (Gaucher's disease)	187
TSD (Tay-Sachs disease)	105
Pax3 (hearing, pigmentation)	47

Alzheimer's disease, some cancers, autism, epilepsy and bipolar disorder, among others, have been identified but typically the findings are restricted to a small number of families or isolated populations; there is often evidence that risk can be attenuated or exacerbated by environmental exposures, and identified genes generally explain only a small fraction of cases.

Two of the primary criteria used to test hypotheses in science are *induction* and *falsification*. Epidemiology and human genetics rely on the inductive approach of *replication* to confirm hypotheses, viewing failure to replicate as a form of falsification. However, it is not easy to apply these criteria in practice, because contradictory results are so common in the study of complex diseases, and difficult to interpret. When two studies disagree, for example as to whether a given nutrient is a risk factor for a type of cancer, it may indicate that one study is wrong, with the possible reasons ranging from chance sampling effects to poor study design, poorly chosen controls, confounding, bias, artifact or inadequate sample size or technology, or measurement errors. On the other hand, the discrepant results might accurately reflect true differences between the samples. There is no clear, single explanation.

One tactical response has been to study a complex trait in a small population isolate, where causation may be simpler because bottlenecks in ancestry may reduce genetic heterogeneity. One risk is that a causative allele found in such an isolate may be rare or absent in other populations. Another response is to greatly augment sample size by combining results of many studies in a meta-analysis (Ioannidis *et al*., 2001; Lohmueller *et al*., 2003; Munafo and Flint, 2004). The typical result is an increase in heterogeneity and the diminution or disappearance of evidence of the effect of a given genetic factor. One reason for this is that genome-wide mapping studies that initially report an effect have inherent bias in terms of sampling high-risk families or individuals, the simultaneous testing of hundreds of independent markers, and other artifacts (Goring *et al*., 2001; Terwilliger and Weiss, 2003).

The risk for some complex diseases may eventually be largely accountable in terms of specific genetic or environmental factors, while others will remain poorly understood and unpredictable, particularly if the ultimate goal is individual risk prediction. Complex diseases are caused by many risk factors, and the nongenetic ones may have strong secular trends (as most risk factors for common diseases have had over the past half-century). If individual factors have individually small effect, and causation is heterogeneous, and if risk is a probability assessed on population data yet every individual is unique in terms of his or her genome and lifetime environmental exposures, the task of predicting risk on a case by case basis becomes manifestly more complex, if not close to impossible.

5. Current issues and prospects

Causal complexity seems to be well understood in principle, but each case presents an epistemological quandary when it does not easily parse into replicable causal components. If the reality of complexity is acknowledged, and, for example, each family or population isolate has a unique pathway to disease, it becomes difficult to know what biomedical approaches would be effective for preventing disease, and the goal of identifying individual risk with rigor or accuracy may be unachievable, or too costly for the gain in knowledge.

It is very expensive in terms of the number of genetic markers, sample sizes, meta-analyses and the like even to *detect* genetic factors and probably even more difficult and costly to identify environmental factors or interactions with small effect on risk.

An inherited genotype is present from birth, but exposure to environmental effects that may interact with that genotype is often gradual. Therapeutic or public health decisions are based on prospective risk, to the *next* generation, but based on studies of the effect of *past* exposures. Yet it is very clear from the past century of epidemiological research that major, relevant environmental changes are always occurring and the *future* regimes of exposure are largely unpredictable. Not only does this cause problems in practice but it also clearly shows the elusive nature of the basic concepts of causality in this field.

The evidence of global prevalence distributions and secular trends shows that for many complex diseases, such as diabetes, cancer, cardiovascular disease, obesity, and others, trends to “westernization”' of lifestyle have similar general effects worldwide. This does not mean that genetic variation is uninvolved, but from a public health point of view, focus on the physiological funnel points is likely to have greater effect than focus on individual genetic causes. Genotypes that lead to early onset or that are less sensitive to the environment will be suitable targets for intervention, but will generally be much rarer.

The problems associated with decomposing complex traits into their genetic and other causes are challenging, but this does *not* always reflect a lack of scientific understanding of such traits. Indeed, the general role of genes in complex traits has been known for almost a century. Advances in molecular genetic technology over the past 20 years have made it possible to document the general validity of that theory, and the results of thousands of studies of the genetics of complex traits

are also consistent with what we know about the way evolution works (Weiss and Buchanan, 2003). This is a triumph of modern science, even if it does not provide easy answers. Complex traits are what they seem: complex.

Specialist Review

The common disease common variant concept

Deborah S. Cunninghame Graham and Timothy J. Vyse
Imperial College, London, UK

1. Introduction

Unraveling the genetic basis of human diseases represents a major challenge in human genetics. This is especially the case for complex diseases, which comprise the bulk of the disease burden in industrialized societies. Complex genetic disease traits arise as a consequence of genetic and environmental contributions to disease susceptibility (*see* Article 58, **Concept of complex trait genetics**, Volume 2). The genetic component is split across many loci, each contributing a small effect to the overall susceptibility. Thus, the identification of the causal genetic variants in these diseases presents a major challenge to human geneticists. The problems of achieving this goal are further magnified by the complexities that result from the gene–gene and gene–environment interactions.

Linkage mapping has been used to great effect with simple Mendelian disease traits, such as cystic fibrosis (Pritchard and Cox, 2002) where genetic variants in a single gene increase the risk of disease dramatically. The nature of complex traits is such that the identification of disease susceptibility genes has relied heavily on association methods. Whether of case–control design, or family-based design, the successful outcome from association studies is dependent on the presence of linkage disequilibrium (LD) in the genome. When a novel variant first appears, it will create a new haplotype, the constituent markers of which will be coinherited for a number of generations. During this stage, it is possible to predict the identity of the other alleles by identifying the allele at one marker on the haplotype. It is this genetic predictability that is exploited in LD mapping, before recombination events occur, which will, over time, cause the overall pattern of LD in this new haplotype to start to break down, thereby reducing the predictable nature of the pattern of inheritance. The pattern of LD across the genome, therefore, has a major impact on the interpretation and design of association studies. The efficacy of an association study to identify a given disease-susceptibility locus is also influenced by the number of alleles at that locus that contribute to disease risk. How many susceptibility alleles there are at any given disease locus depends on their allele frequencies and the allelic heterogeneity. The number of different variants present

within a locus that predispose to a disease phenotype may be referred to as its allelic diversity or the allelic spectrum. The term genetic architecture has been used to refer to the range of allelic diversity in the genome that will contribute to a phenotype. Obviously, the genetic architecture will have an impact on the statistical power of mapping studies to detect positive associations. In single-gene disorders, the allelic spectrum can be wide, but the penetrance of the alleles is maintained. In polygenic disease traits, the complexity of the allelic spectra and the genetic architecture will influence the feasibility of identifying disease susceptibility alleles. A large number of loci, each with complex allelic spectra would severely compromise the probability of finding susceptibility alleles in polygenic disorders. Success would require both larger study cohorts and very large numbers of polymorphisms to be typed (Wang and Pike, 2004). However, it can be argued from a theoretical standpoint that more common allelic variants may predispose to complex polygenic diseases: the common disease–common variant hypothesis. Preliminary data from association studies in complex traits suggest that commoner variants do make some contribution to disease. The arguments behind the common disease–common hypothesis will be described and some examples provided. We will also discuss alternative models and suggest that the true nature of the architecture of genetic disease will reflect more than one single concept.

2. The concept of genetic architecture

When considering the penetrance and number of alleles that predispose to disease, it is useful to consider the influence that quantitative variation in these parameters will exert on the ability to find and identify causal disease polymorphisms (*see* Article 10, **Measuring variation in natural populations: a primer**, Volume 1). Genetic disease can be divided into monogenic disorders and polygenic or complex disorders. Monogenic diseases are usually rarer and result from the inheritance of highly penetrant genetic variants at one or a very limited number of loci. More than 1500 monogenic disease genes have been identified, and it is well established that the majority of such diseases exhibit marked allelic diversity (On-line Mendelian Inheritance in Man **http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM**). The degree of allelic heterogeneity in any population will reflect a balance between the processes of spontaneous mutation and selection against the inheritance and propagation of any allele. The rate of spontaneous mutation in the genome is highly variable: estimates vary from 10^{-4} to 10^{-7} per locus per generation (Bellus *et al*., 1995; Crow, 2000; Eyre-Walker and Keightley, 1999). There is no compelling evidence, however, that simple Mendelian disorders arise in genes that exhibit particularly high-mutation rates. However, in comparison with complex genetic conditions, monogenic diseases are more likely to exert some influence on survival, and hence, selection is more likely to operate in a population in relation to monogenic disease when compared with complex genetic disease. How might the allelic diversity in monogenic disease be explained? It is imperative in the consideration of such issues to incorporate the fact of the rapid expansion of the human population over the preceding millennia. The exact number of millennia is open to debate; best estimates suggest that this population explosion has occurred over the preceding

700–6000 generations; that is, in the range of 18 to 150 millennia. This impressive demonstration of fecundity has had a major impact on the genetic architecture of the modern human population. The dramatic increase in population size would be expected to increase the numerical representation of disease alleles, even rarer ones, in modern humans. However, two factors will serve to reduce this effect and lead to marked allelic diversity in monogenic disease. First, as new mutations are generated they are less likely to arise on a preexisting disease-associated haplotype, if that haplotype itself is uncommon. Thus, for rarer disease alleles, the accrual of mutations over generations is likely to simply expand the number of disease susceptibility alleles. Second, the presence of selection will serve to reduce the frequency of causal alleles over time.

Not all monogenic diseases demonstrate marked allelic diversity. Several factors may explain this situation. Most simply is the case of heterozygous advantage. In this scenario, alleles whose pathologic effect is biased toward recessivity can confer a selective advantage when present as a single copy. There are several well-characterized examples of polymorphisms that exhibit some degree of protection from malaria, for example, G6PD deficiency at the *G6PD* locus, and HbC and HbS at the *HBB* locus in West African populations; the estimated allele frequencies being 0.20, 0.09, and 0.10, respectively. Selection may operate during the phase of population expansion, and it may increase the frequency of certain alleles in the population in the preexpansion phase. For example, the mutations that give rise to cystic fibrosis (CF) do not immediately appear to comply with the arguments set out above. More than 900 alleles of the CF transmembrane conductance (*CFTR*) gene have been associated with CF, however, approximately 70% of cases are due to one single deletion, ΔF508. It has been postulated that heterozygotes carrying *CFTR* mutations may have some selective resistance to *Salmonella typhi* (Pier *et al*., 1998). Irrespective of the mechanism, it can be shown that for an allele as frequent as ΔF508 in the preexpanded population this simple ancestral spectrum will persist following expansion with a half-life of 39 000 to 390 000 years, depending on the assumed mutation rate (Reich and Lander, 2001).

Do the effects of recent population expansion differ in complex traits when compared with monogenic disorders? If one assumes that the frequency of the disease susceptibility alleles in more common complex genetic traits is higher than in rare monogenic disease, then essentially the answer is yes. And not only is the answer in the affirmative, but it was shown by Reich and Lander that this situation will remain so for tens if not hundreds of thousands of years, depending on the frequency of the disease allele. Unsurprisingly, more common alleles persist at a similar frequency in an expanded population for longer. The implications of this model have given rise to the common disease–common variant hypothesis.

3. Current hypotheses to explain genetic architecture

3.1. Common Disease Common Variant (CDCV) hypothesis

The CDCV, or interactive, model of genetic architecture was first proposed in 2001 (Reich and Lander, 2001). It states that complex diseases are caused by the

interaction of common alleles at a small group of susceptibility loci (Smith and Lusis, 2002; *see also* Article 57, **Genetics of complex diseases: lessons from type 2 diabetes**, Volume 2). These common alleles are not population specific, but are present at >1% minor allele frequency in multiple populations.

By taking into account the rapid, recent expansion of the human population, as described above, it is apparent that the allelic spectrum at all loci will gradually increase with time. However, the frequency of the allele in the preexpansion phase is critical to the rate at which allelic diversity is generated. Mathematically, the main influences on the allelic spectrum, in the absence of selection, can be summarized as a balance between the forward mutation rate, $4N_e u_s$, and the reverse mutation rate, $4N_e u_n$, where N_e is the effective population size (usually estimated to be 10 000) and u_s is the mutation rate per generation per locus, the n subscript denoting the reverse mutation rate. That is, in any stable population, where the genetic variants are in equilibrium, there is a balance between the rate at which new mutations arise, which for most genes is at a rate of approximately $1 \times 10^{-5} - 1 \times 10^{-6}$ per gene per generation (Bellus *et al*., 1995; Crow, 2000; Eyre-Walker and Keightley, 1999; Peltomaki, 2001; Sankaranarayanan, 1998) and their loss by negative selection. However, in a rapidly expanded population, rare alleles in the original founder pool are reduced in frequency as the result of strong selective pressure, and will become swamped by the generation of new alleles (Reich and Lander, 2001). By contrast, common alleles, which have a large population reservoir, and are under little selective pressure, have a lower turnover, so will take longer to be diluted out (diversified) by the presence of these new mutations (Smith and Lusis, 2002). New disease-susceptibility mutations might arise but they would still be carried on the ancestral haplotype. The higher the initial allele frequency, the longer this will take (Wright and Hastie, 2001). Allele diversification will continue in this way, until the alleles reach equilibrium in the expanded population. Reich and Lander state that the diversification of the alleles in the expanded human population is in an intermediate stage, so that these selectively neutral common alleles that were important markers of disease in the preexpanded population are predicted to have retained a low level of allelic diversity in the postexpansion human population. Therefore, they can still be useful markers of common disease in the modern human population (Smith and Lusis, 2002). These concepts are illustrated in Figure 1.

Another important factor in formulating the CDCV hypothesis is the strength of the selection pressure on allele diversification. For alleles to attain a high-equilibrium frequency in a population, that is, retain low diversity and be useful markers in LD mapping of complex diseases, they must be selectively neutral or be under low-selective pressure. This leads to a lower turnover in the population and decreases the effect of new mutations. However, selectively neutral alleles are likely to make a small contribution to the overall disease risk, giving weak associations to disease, which will be another factor in the requirement for large samples size. This situation might be the case for alleles implicated in disorders such as for late onset diseases such as type 2 diabetes (T2D) or hypertension (Wright and Hastie, 2001). Furthermore, it is necessary to take into account stratification issues when interpreting association study results. An allele may be at a high frequency in a subpopulation, due to urbanization or geographical isolation, so a positive or negative association may not be applicable to the population as a whole. The

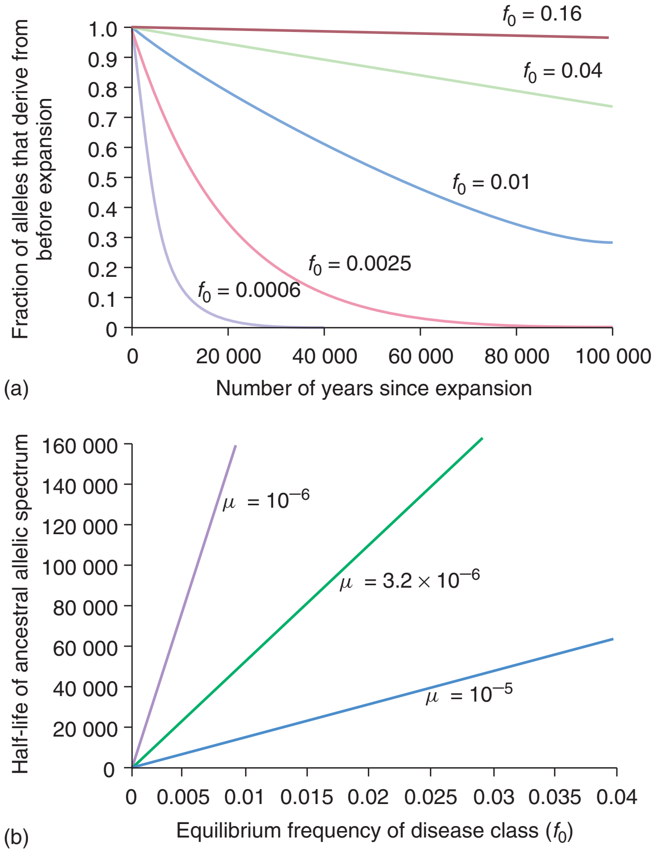

Figure 1 This Figure is taken from the paper by Riech and Lander. It illustrates the change over time accompanying the human population expansion of the frequency of the disease-susceptibility alleles, f_0. How the fraction of the total proportion of disease-susceptibility alleles changes with time is shown in (a). The curves are calculated assuming a population increase from 10^5 to 6×10^9 and a fixed mutation rate (μ) of 3.2×10^{-6} per generation. As is shown, more frequent classes of disease alleles will have persisted over the preceding 100 000 years and shown only a slight reduction in frequency. The same point is illustrated in (b). In this graph, the time taken for the original disease allele class frequency to fall by half is shown. Thus, for a disease allele frequency of 0.005, the frequency will have fallen to 0.0025 after approximately 20 000 years. It can also be seen that at higher-mutation rates (μ), the half-life is substantially shorter. The probability that the two alleles randomly picked both belong to the disease-susceptibility class is denoted by ϕ_{disease}. Hence, the reciprocal of this term is an index of the allelic spectrum of any disease. In (c), an arbitrary threshold for simpler disease spectra is shown by a cutoff of $1/\phi_{\text{disease}} = 10$. The simpler disease spectra are maintained for at least 100 000 years with disease allele frequencies between 0.01 and 0.05 (Reprinted from *Trends in Genetics*, vol. 17, Reich DE, *et al*, On the allelic spectrum of human disease, pp. 502–510, Copyright 2001, with permission from Elsevier)

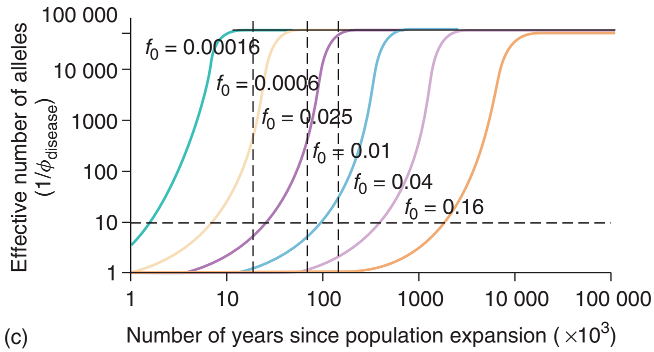

Figure 1 (*continued*)

influence of the rapid expansion of human populations may also be seen in relatively isolated populations. In such circumstances, there may be a marked influence of the chromosomal composition of the founders of that population. Indeed, as can be seen in Figure 1, if this "founding" effect occurred relatively recently, then even low-frequency disease-susceptibility alleles may be disproportionately represented in the contemporary population.

The CDCV model predicts that there is an increased risk for common diseases from common variants of low individual risk, across multiple populations. Three examples of common alleles supporting this hypothesis are: a 32-bp deletion in the coding region of the *CCR5* gene, which decreases the transmission of HIV-1, has an allele frequency of at least 9% in Caucasians (Wright and Hastie, 2001), and is common in a number of other populations (Lu *et al*., 1999); the E4 allele of Apolipoprotein E (*APOE*), which has a prevalence of 15% in Caucasians, over 20% in Africa and Scandinavia, and 6–12% in Japan and China (Ritchie and Dupuy, 1999) has been associated with Alzheimer's disease (Saunders *et al*., 1993) and coronary artery disease. A common variant, P12A at the *PPAR*γ locus is associated with type 2 diabetes (Altshuler *et al*., 2000). The causal allele is at high frequency in the population (0.85) and as expected the risk associated with it is small. The genetic basis of complex disease is insufficiently established, however, to provide full empirical support to the CDCV hypothesis. It should also be appreciated that association studies have a bias toward identifying more frequent variants.

3.2. *Multilocus-multiallele hypothesis*

However, the CDCV hypothesis does not provide the complete answer to the nature of the genetic architecture of human populations. The CDCV hypothesis states that the common diseases are due to common alleles, but the multilocus-multiallele (MLMA) or genetic heterogeneity hypothesis describes complex diseases as having a low probability of carrying a given susceptibility allele, given the fact that these diseases have a contribution from multiple susceptibility alleles and environmental influences. This gives a low chance, or low detectance, of detecting a single deleterious allele during an association study (Weiss and Terwilliger, 2000).

Furthermore, the high frequency of some complex diseases could be due to the prevalence of environmental triggers that form part of the natural aging process. For some complex diseases, for example hypertension, there is a high-level contribution of environmental/natural aging factors implicated in the disease process, since the heritability decreases with increasing age of onset, due to an increasing contribution from the aging process and other environmental factors.

One more factor supporting the MLMA hypothesis is a predictor that low-frequency variants have a role to play in the genetics of a disease, rather than the high-frequency variants proposed by the CDCV hypothesis. This predictor arises from the inverse relationship between allele frequency and genetic effect (Morton, 1996; Wright, 1968) and proposes that the lower the allele frequency, the higher the genetic effect. Evidence from breast cancer and familial hypercholesterolaemia (FH) are two examples that support the idea of rare alleles being important risk factors for disease. In the *BRCA2* gene, there are greater than 404 rare alleles with increased risk of disease, but only 1 out of 6 common alleles have any effect. Likewise, in FH, there is an increased risk of premature coronary artery disease attributed to more than 435 rare alleles in LDL receptor, but no known common alleles (Wright and Hastie, 2001).

These examples also serve to raise the question over what proportion of weakly associated, selectively neutral common alleles actually have a role to play in the genetic aetiology of complex diseases. Since it has been proposed that neutral alleles either tend to be lost to a population or be fixed in that population (Pritchard and Przeworski, 2001) and common alleles are thought to attain their high-allele frequency by virtue of being selectively neutral, they are unlikely to have a significant effect on risk of disease (Pritchard and Przeworski, 2001).

3.3. Selection in complex traits

As may be predicted by the CDCV hypothesis, the E4 allele of *APOE* appears to be the ancestral allele (Fullerton *et al*., 2000) and is not uncommon the population. The situations at *PPAR*γ locus and in the VNTR alleles at the *INS* (Insulin) locus are analogous. Why should disease-susceptibility alleles be so prevalent in the population? The model of recent population expansion predicts their high frequency in the ancestral population. It could be argued that their individual disease risk is small, often complex disease traits pertain to diseases of adult onset that may impact less on selection. It is also possible that there are some selective advantages to alleles that predispose to complex traits (Fullerton *et al*., 2000). It was suggested more than 40 years ago that diabetes mellitus might be so common in the modern world as a consequence of the selection of alleles conferring metabolic efficiency on the bearer (Neel, 1962). Similarly, it can be argued that autoimmunity may arise as a consequence of the selective pressures imposed by infection.

3.4. Common variant/multiple disease hypothesis

The CDCV hypothesis also lends itself to extension, raising the possibility that common disease variants may predispose to multiple diseases. That is, if a restricted

number of common genetic variants predispose to a disease state, would this mechanism be disease specific? The overlap between many complex disease traits is well established at an epidemiological level, although often less well understood pathologically. It would not be surprising to learn that coronary artery disease (*see* Article 63, **Hypertension genetics: under pressure**, Volume 2), obesity, and type 2 diabetes shared some common aetiology. It is apparent that multiple autoimmune diseases appear to be more prevalent in some families (Broadley *et al*., 2000). Indeed, there is genetic evidence to support the concept of shared genetic risk factors in different, but related disease states. For example, it has been shown in autoimmune diseases that the loci mapped in genome-wide linkage studies tend to overlap more than would be anticipated by chance. This observation has also been made in animal models of autoimmunity (Becker, 2004). Similar observations have been made in schizophrenia and in bipolar disorder, and in type 2 diabetes and obesity. Linkage analysis defines large genomic regions that do not necessarily harbor identical disease alleles. The lack of well-substantiated disease associations in complex traits does not allow clear support of commonality of genetic factors. However, there are some tantalizing clues. The E4 allele of *APOE* has been cited in support of the CDCV hypothesis, above, the association with Alzheimer's disease and coronary artery disease suggest the possibility of shared genetic factors, a conclusion strengthened by the association of E4 with other related disease states (Smith, 2000). Similarly, *CTLA4* polymorphisms have been reported to be associated with multiple autoimmune diseases including type 1 diabetes, multiple sclerosis, and autoimmune thyroid disease. The heterogeneity of the published data and the complexity of *CTLA4* haplotypes are such that it is unclear at present whether these *CTLA4* associations represent the influence of a common or restricted number of causal variants.

4. Conclusions

Much of the progress in LD mapping of complex diseases has been made using the major assumptions of the CDCV hypothesis, that is, that common alleles cause common diseases. However, the results are often inconclusive, with reports of negative or borderline associations, and positive associations, which are frequently population dependent. There are many reasons for these findings. There is probably an overall lack of power in the individual studies, so that association is biased toward the identification of more common, but weaker haplotypes. However, the failure to find widespread, reproducible association using LD mapping is not a reason to discard the CVDV model as a working hypothesis. The CDCV model does not have to be universally applicable to justify its use in LD mapping studies (Goldstein and Chikhi, 2002). However, the results of such studies need to be interpreted with caution. If negative results in an LD-based mapping study, that is, no common alleles are associated with disease, then it is worth going back to the data and looking for rare variants. For positive associations with common alleles, it will be necessary to first gain replication of the results in an independent sample set and then look for rarer SNPs, with potentially greater penetrance, which may have been overlooked in the initial study. It is likely that the true genetic architecture includes

a combination of both rare variants and common alleles, potentially in the same locus, making a genetic contribution to disease, since that is the pattern of allele frequencies across the rest of the genome (Wang and Pike, 2004). Furthermore, it seems unlikely that there are multiple common alleles interacting with one or more common environmental triggers to cause common diseases and that these disorders are not even more prevalent. One solution to this problem is that common diseases require an additional contribution from rarer, more penetrant alleles, with increased disease risk to "tip the balance". For the future, the full potential of the CDCV hypothesis and LD mapping is unlikely to be realized unless the contribution of rare alleles is assessed through fine mapping in large collaborative projects.

Specialist Review

Population selection in complex disease gene mapping

Teppo Varilo and Leena Peltonen

National Public Health Institute and University of Helsinki, Biomedicum Helsinki, Helsinki, Finland

The Broad Institute at MIT and Harvard, Boston, MA, USA

1. Introduction

Perhaps one single most critical choice in any complex disease gene mapping efforts is the selection of the study population. Nonetheless, geneticists often tend to neglect the optimal study design, and too often turn to population samples offered to them more or less by chance. Following the path of the feasibility and least resistance has often translated to the use of case-control samples from heterogeneous, less-ideally characterized study populations. Thanks to the human genome project, the scientific community has now excellent tools for the identification of specific alleles associated with any disease process. High throughput genotyping of multiallelic Short Tandem Repeat (STR) or biallelic (SNP) markers can be used to define the genetic profiles of DNA samples with a high accuracy. However, the exponentially advancing technical capacity is wasted if blindly utilized for inadequately characterized study samples. The detailed information of the character and history of the target population has a major impact on the study design and on the interpretation of the obtained results. Differences in demographic history of the isolated populations demand divergent research strategies and also dictate the selection of markers and statistical methods to be used in initial genome scans and in the subsequent positional cloning aimed at the identification of allelic variants. A failure to take into account in association studies the extended-familial relationships, typical for isolated populations, can produce false–positive results, missing true associations while overestimating the level of significance (Newman *et al*., 2001). Most initial findings of predisposing genes of complex traits have been substantiated only in extremely well-designed study samples, often representing families or study samples of special populations with exceptionally high loading of a disease, exposing distinct genetic character of a trait (Hugot *et al*., 2001; Mira *et al*., 2004).

Population isolates offer an avenue for a cost-effective initial identification of complex disease loci, and if wisely utilized, have tremendous potential also for the final identification of specific disease alleles. The isolates simplify the genetic

background of polygenic diseases since they show a restricted number of involved genes and their alleles. In typical isolates, a founder effect, genetic drift, and isolation of varying period of time have molded the gene pool, resulting in the enrichment of some disease alleles. Some population isolates provide the research conditions comparable to those accomplished with inbred animal strains. In an ideal case, families gathered from population isolates show, in addition to a higher genetic homogeneity, also social cohesion and restricted amount of environmental and cultural diversity, not achieved in outbred populations. Further benefits of ideal population isolates include accurate genealogical records, standardized health care, and reliable medical information. All these features greatly facilitate the collection and assembly of powerful study samples, identification of cases with shared ancestors (shared genetic background), and systematic compilation of clinical data, including longitudinal quantitative information of various phenotypic features.

2. The concept of an isolate

Multiple bottlenecks and repeated periods of genetic drift characterize the history of human populations, and the diversity of the human genome is significantly less than intuitively anticipated. In early times, the human population expanded in size as it inhabited the wilderness. The waves of migration involved typically small groups, first out of Africa about 100 000 years ago (Cavalli-Sforza, 1998) and some 50 000 to 30 000 years ago, into new regions, such as the Americas and Australia. A third wave of migration and growth occurred about 10 000 years ago after the last glacial period with the spread of agriculture from the Middle East. New subpopulations isolated by distance were eventually established even in the most peripheral regions of the world during the written historical times. In addition, the extreme environmental changes such as famines, wars, and epidemics of infectious diseases, and even social factors such as religion or sources of livelihood have created recent, efficient bottlenecks, restricting the regional allelic diversity. The subsequent population expansion of some global isolates is often accompanied by relative inbreeding lasting for tens of generations, causing a reduction in the effective population size and further reducing allelic diversity.

Unfortunately, for most global isolates, we lack reliable information on their initial genetic makeup, their total number of founders, and the extent and duration of their isolation. Only a handful of isolates such as Quebec, Iceland, Northern Sweden, or Finland, and some special religious populations have easily accessible and reliable genealogical records, which date back to the establishment of the population, offering a helpful tool for complex disease gene hunt based on the assumed sharing of disease alleles among affecteds. We can roughly infer the extent of a population's isolation by its trademark monogenic diseases. Younger isolates tend to have distinct spectrum of such diseases like exemplified by the Finnish disease heritage (**www.findis.org**). As expected, the genealogy of older isolates is more complicated and the enrichment of specific diseases less remarkable.

A very small number of founders for a population provide a significant advantage for disease gene mapping efforts (Kruglyak, 1999; Wright *et al*., 1999; Johnson and Todd, 2000). Linkage disequilibrium (LD), a strong association between

markers on the alleles originating from the same historical ancestral chromosome, is detectable over wide genetic intervals in young isolates. Using multiallelic markers, the disease alleles of such isolates can expose LD intervals reaching 10 Mb, whereas in older isolates, the extent of LD intervals is not different from more heterogeneous populations, reaching just a few kilobases. For rare monogenic diseases, the standard genome-wide scans with some 400 multiallelic markers have typically exposed a significant linkage disequilibrium in disease alleles of isolated populations. This has facilitated an efficient identification of disease loci in very small study samples (Houwen *et al*., 1994; Nikali *et al*., 1995). The subsequent haplotype sharing strategy with a denser set of markers has provided powerful restriction of the critical chromosomal region to manageable intervals for sequencing. The same strategy has also worked for some common traits in genetic isolates. In lactose intolerance, a single nucleotide polymorphism (SNP), a C to T change residing some 14 kilobases upstream of the lactase (LCT) gene on 2q21-22, was found to exhibit a complete association with lactase persistence (Enattah *et al*., 2002). This variant, interfering a cis-acting regulatory element, was uncovered in an exemplary set of Finnish families descending from an isolate where LD and haplotype analysis could be relied upon. The result has been subsequently confirmed in outbred populations, enabling a global diagnostic test. We, among others, have shown that in general (nondisease) alleles of young (10–20 generations old) subisolates, the size of LD intervals reaches up to 1 Mb, and this feature most probably offers an avenue for the initial locus positioning for complex traits in these populations.

So far, most findings of complex disease genes have been based on the linkage studies in rare families with multiple disease cases. These studies have yielded initial evidence for disease loci, but for most cases, verification of the locus finding in different populations and the final identification of the gene has remained a problem. As expected from the anticipated allelic and locus heterogeneity of these diseases, differentiating the genuine loci from the statistical ghosts has been very complicated even within the best-characterized study samples. However, some population isolates have disclosed encouraging allelic associations for complex diseases, often since they have facilitated efficient sample collection and careful phenotyping (see Table 1).

3. Considerable dissimilarity of isolates

Not all isolates are alike – even Finland has subpopulations emerging from various founder populations. Globally, the isolates vary in crucial aspects. The number of founders, the age of the population, the expansion rate, the historical bottlenecks (famines, wars), and amount of immigration, all affect the extent of the diversity in disease (or any) alleles of the given population. Furthermore, successful genetic studies of complex traits, with a multigenetic background, require a sufficient population size to offer adequate study samples and to expose the complete genetic background of any trait. However, even very small isolates originating from a handful of ancestral chromosomes might turn out to be extremely valuable for the initial identification of individual, important, but most probably family-specific,

Table 1 Some promising gene associations in complex diseases

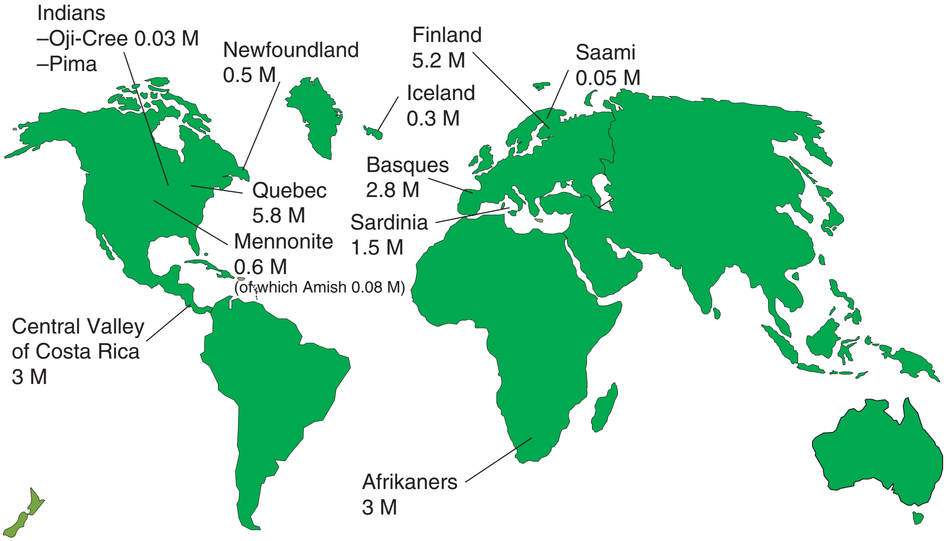

Figure 1 A global view to some interesting, well-characterized population isolates. The biggest populations here are in Quebec, Finland, Costa Rica, and South Africa

high-impact disease alleles. They will expose pathways of general significance for the clinical phenotype and thus disclose new targets for research. The better the characteristics of the populations and their history can be established, the better are the opportunities to design the optimal strategy for the disease-gene identification. An extra bonus is obtained from an access to the detailed population records, which facilitate construction of mega pedigrees and identification of families with shared ancestral alleles. Self-evidently, homogeneity in life style and environment facilitate the control of these intervening factors. Often, geneticists tend to focus on populations with an extraordinary high prevalence of the disease of interest, but for complex diseases, this might reflect not only genetic but also environmental effect. On the basis of the good experiences of gene identification for rare diseases, one might actually argue that a population with an exceptionally low prevalence of a complex disease might present a special opportunity for gene identification. In Figure 1, we provide a global view to some population isolates with a reasonable size, most of them already utilized in complex disease gene mapping efforts with promising results, some still representing a highly potential option for future studies.

4. Statistical methods

For the initial mapping of Mendelian traits, linkage analysis has proved remarkably successful (Wright *et al*., 1999). Linkage analysis evaluates the recombination events occurring within a sample of pedigrees under a precise model of the inheritance for the trait. The evidence in favor of linkage is summarized by the lod (logarithm of the odds) score plotted against the recombination fraction separating the disease locus and a nearby marker locus. The position of the linkage peak is

usually taken as an estimate of the genetic distance between the marker and the actual disease gene. In isolated populations, this initial positioning of the disease locus can be followed by fine mapping positioning accurately the disease gene based on the shared haplotype among affected individuals, originating from one founder.

With common diseases, the situation is less favorable both for initial positioning using linkage analysis and for final positioning of the disease locus linkage analysis. The genetic model for the trait cannot be well defined in linkage analysis, and genetic heterogeneity quickly erodes the statistical evidence for linkage for any single locus (Greenberg *et al*., 1998). Also, the initial positioning of the disease locus is not accurate. The position of the linkage peak is highly dependent on the parameters applied, and the incomplete penetrance of the disease genes results in broad linkage peaks, providing very little guidance of the actual position of the gene (Hovatta *et al*., 1998; Terwilliger, 2001). However, most studies have used linkage analysis in exceptional muliplex families, assuming a monogenic disease model with reduced penetrance (Clerget-Darpoux *et al*., 1986). The extremes of dominant and recessive models for inheritance are thought to cover most cases of family-ascertained study samples. However, nonparametric allele-sharing methods, avoiding explicit assumptions about disease transmission, are favored over parametric linkage analyses (Kruglyak, 1996; Sobel and Lange, 1996). If the affected individuals within a collection of selected pedigrees or sibships show an excessive sharing of marker alleles in a particular chromosomal region, that region is likely to harbor a disease gene. The power of parametric versus nonparametric methods depends strongly on how strong is the genetic element of the disease. For both parametric and nonparametric methods, isolated populations obviously offer an advantage because isolation limits genetic heterogeneity.

Association studies can be divided into case-control studies and familial tests of transmission distortion. In genome-wide scans even with an atypically high density of the markers, the association is the by-product of linkage disequilibrium. By contrast, the alleles at a candidate locus may directly influence the risk of disease. In a genetically homogeneous population, case-control studies involve straightforward comparison of allele or haplotype frequencies in random samples of cases and controls, both ascertained from the same (sub)population (Risch and Merikangas, 1996). In heterogeneous populations, with inbuilt problems of the population stratification, association studies rely heavily on the transmission-disequilibrium test (TDT) (Terwilliger and Ott, 1992; Spielman *et al*., 1993). TDT compares how parental alleles are transmitted or not transmitted to affected children and evaluates whether one or more alleles are preferentially transmitted to the affected children. Although the TDT method was originally recommended for independent trios of both parents and an affected child, versions of the TDT exist for sibships and even pedigrees (Allison *et al*., 1999; Boehnke and Langefeld, 1998; Spielman and Ewens, 1998; Schaid and Rowland, 1998; Teng and Risch, 1999). With parametric versions of the TDT, it is possible to combine case-control data and familial transmission data into a single analysis that checks both differences in allele frequencies and distorted transmission to children (Sinsheimer *et al*., 2000).

Analogous to linkage mapping, population isolates have certain advantages over outbred populations in association studies. The uniform genetic and environmental background of a population isolate makes case-control studies less suspect.

Population isolates and outbred populations depart from genetic equilibrium in different ways. Hardy–Weinberg equilibrium, which is more likely in a population isolate than in a population with considerable racial admixture, helps in testing differences in allele frequencies between case and controls.

Haplotype mapping has the advantage of revealing ancient recombination events in addition to the contemporary recombination events detectable by linkage mapping. Linkage mapping operates best on a coarse scale where haplotype signatures are lost. Thus, it is sensible to view linkage and haplotype mapping as complementary techniques. The usual strategy is to use linkage mapping to identify a candidate region and then to follow up with haplotype mapping to pinpoint the disease locus within that region (Jorde *et al*., 2000; Peltonen, 2000). If a good candidate gene, based on the known biology, is suspected in advance, it is possible to reverse the standard procedure and test first for association between the disease and alleles at the candidate gene or nearby markers. In practice, most geneticists hedge their candidate gene bets by including these genes as markers in a genome scan. New methods providing efficient SNP genotyping and rapidly increasing information of the LD intervals and SNP haploblocks in different populations are paving the way toward genome-wide haplotype-association studies (see later).

Efforts have been made to quantify the extent of LD around a disease gene and using this as a guide to positional cloning. Inference from any single marker tends to be unreliable. Because of differences in the information content of the markers and the high probability of a by-chance association of a disease-causing variant with the marker allele, single-marker measures of disequilibrium do not greatly contribute to the final positioning of a disease gene. This fact has prompted the development of multimarker measures of disequilibrium and model-based methods of analysis that exploit these measures (Collins and Morton, 1998; Devlin *et al*., 1996; Kaplan *et al*., 1995; Lazzeroni and Lange, 1998; McPeek and Strahs, 1999; Rannala and Slatkin, 1998; Terwilliger, 1995; Xiong and Guo, 1997). Furthermore, informativeness of the marker has a distinct impact on the detection of intermarker LD. In the Finnish subisolate, the marker pairs of most informative microsatellite markers exposed intermarker LD over wide intervals reaching 7.5 cM, whereas less-informative SNPs revealed significant LD over very limited intervals, typically less than 0.1 cM (Varilo *et al*., 2003).

Much enthusiasm and debate surrounds the potential of the international high-profile Haplotype Map (**www.hapmap.org**) project and its ability to guarantee a high resolution of allelic variants for complex disease gene mapping even in association-based studies (Daly *et al*., 2001; Weiss and Clark, 2002; Wall and Pritchard, 2003; Terwilliger and Weiss, 2003). So far, the studies addressing the diversity of haploblocks have been carried out in a highly limited number of populations. It is not a surprising finding that the extent of intermarker LD with SNPs is much less and the haploblocks more diverse in African populations than in the younger global populations. The average interval showing strong evidence of recombination was found to be only 8 kb in Yoruban (from Nigeria) and African–American samples compared to 22 kb in the European and Asian samples (Gabriel *et al*., 2002). Similarly, LD was observed over 5 kb in Yorubans versus 60 kb in US population of North-European ancestry (Reich *et al*., 2001). The size of

haploblocks constructed using common SNPs varies from a few to several hundreds of kilobases and the sizes are greatly variable in different chromosomal regions. Although the statistical methods addressing the true significance of the observed haploblocks are still under construction, the number of haploblocks is typically higher. Gabriel *et al*. (2002) reported 5 common haploblocks ($>5\%$) in Africans versus 3.5 in other populations. It is important to realize that the outcome of the Hapmap based on the information collected from common SNPs (exposing common haploblocks) will not reveal the full variety of the allelic spectrum in different global populations. More detailed analysis of the distribution of the allelic diversity will be needed to identify deviations in this distribution in disease-associated alleles, and this will require a significant amount of extensive sequencing of different alleles.

5. Diversity of complex disease alleles

Evaluating the amount and nature of the genetic component in complex diseases is problematical. Heritability estimates of any given trait only express the proportion of the phenotypic variance in a study population that can be explained by familial factors. It is often forgotten that the obtained values are influenced by all genetic and shared environmental factors, and their interactions. Thus, the estimates for the heritability do not necessarily provide meaningful information of the feasibility of the genetic mapping studies of a given trait.

Let us consider two extreme models of the genetic background of complex traits: Common alleles of a handful of loci could interact to predispose to a disease. Such alleles would show low penetrance but could impose a significant risk at the population level. Alternatively, rare alleles at several loci can each significantly increase the predisposition to a disease. Such alleles could be family specific, show high penetrance, and would be relatively nonsignificant at the population level. In both models, the locus and allelic heterogeneity would be more restricted in an isolate. However, it is obvious that population isolates are especially valuable for the isolation of rare, high-impact genes since the founder effect and/or bottlenecks have dramatically restricted the number of alleles, making the genetic background closely resemble that of any monogenic disease.

It is plausible that population isolates originating from a small number of founders will expose "population specific" alleles or even disease genes. However, little experimental data exists to support this. Most linkage results disclosed in families from population isolates have been replicated in other populations and when this is not the case, differences in the ascertainment strategy or applied clinical parameters can equally contribute to the obtained results. Gene mapping efforts using multiple populations not only hold the promise of confirmation but also provide more information (more genotyped individuals, more meiotic information), allowing a better definition of the mapped interval containing the gene. It is worth stressing here the advantages of older outbred populations since they expose a shorter range of linkage disequilibrium intervals.

6. Genetic makeup of population isolates

With regard to multifactorial diseases presumably caused by old mutations, some population isolates are suggested to be more valuable than others for genetic studies (Peltonen *et al*., 1999; Wright *et al*., 1999). Isolates such as the Saami (Lapps of Scandinavia) or the Basques of southern Europe are well established, 200–400 generations old, and demographically stable (Terwilliger *et al*., 1998). The Saami forager population of 50 000 is estimated to have been of constant size throughout history, regulated and spread to large land areas by their source of livelihood, whereas agriculture led to a population expansion among the major European populations. However, because of their small size, complicated accessibility, and the paucity of recessive diseases, both Basques and Saamis have so far been largely ignored by geneticists.

For studies of complex traits, conscious geneticists have tended to target recent founder populations (100–200 generations old) such as Finland, Sardinia or Iceland, or even younger population isolates (10–20 generations old) that originate from a small number of founders and have undergone rapid population expansion. Examples are populations of late-settled parts of Finland (reaching northern Sweden), Central Valley of Costa Rica, Mennonite, French-speaking Quebec, Newfoundland, Afrikaners, and some regions of Holland. A modification of this strategy has been to send a field group to a remote, usually very small, rural subisolate to measure all quantitative information of various interested phenotypic features (Williams-Blangero *et al*., 2002; Bulayeva *et al*., 2000). Because of the accelerative internationalization, such populations are gradually vanishing, and it should be our minimum responsibility to gather adequate samples for the complex disease projects in future.

We have scrutinized the characteristics of the alleles of Finnish subpopulations, representing internal isolates of this relatively homogeneous population and found them striking. Although the roots of the population of Finland reach over 2000 years, the internal migration within Finland in the 1500s created regional subisolates. Villages were often established by only a few founder couples, which was a potentially ideal setting for complex gene mapping efforts. The effects of multiple bottlenecks can be demonstrated even today by marked differences in the prevalence of rare disease mutations among regional subisolates (Pastinen *et al*., 2001). Historical routes of many internal migrations can actually be reconstructed using the distribution of these disease alleles and the historical time when the mutation was introduced to the population determined based on the interval over which the markers show LD in the disease alleles (Varilo *et al*., 1996b; Varilo *et al*., 1996a).

In fine mapping of complex disease genes, LD and haplotype sharing should be of special value in population isolates. The LD intervals reflect the history of (sub)populations and emphasize the importance of the detailed population history for the study design in the disease gene hunt. Small, constant-size populations like the Saami can be expected to exhibit LD over large genomic intervals and greatly reduce allelic and haplotype diversity, both owing to genetic drift (Laan

and Paabo, 1997; Laan and Paabo, 1998; Terwilliger *et al*., 1998); such populations may be especially powerful for the initial phase of mapping common trait loci if only adequate study samples are available. The advantages of rapidly expanded population isolates have been based on the research on the 100–200 generations old founder populations such as Sardinia or Western early settlement regions of Finland (Zavattari *et al*., 2000; Mohlke *et al*., 2001). The results might be somewhat misleading since population admixture on these coastal areas could easily have dampened the amount of LD observed (Heutink and Oostra, 2002; Angius *et al*., 2001). There are practical implications of this type of information of specific regional subisolates for the prospect and process of LD-based disease gene mapping in study samples from one population. The long-range LD required for the initial genome-wide mapping exists in young subpopulations, with a well-established population history. Conversely, the LD decay, associated with the older main population, represents an efficient tool for finer-scale gene localization.

7. Isolates provide an avenue for efficient collection of pedigrees

Most successful gene identifications in complex traits (Table 1) have so far been initiated in large pedigrees with carefully defined and often extreme clinical phenotypes and at least to some extent shared environment. This has probably resulted in the identification of somewhat exceptional, "high impact" genes, most of them having a low attributable fraction at the population level. The most extensive example of the systematic use of population history, genealogical records, and nation-wide health care registries in genetic research is the Decode project in Iceland. Although not representing an ideal population isolate (Arnason *et al*., 2000; Helgason *et al*., 2001; Heutink and Oostra, 2002), the excellent genealogical records uncovering extensive pedigrees with shared ancestors for several complex diseases simultaneously have gained momentum for the disease locus mapping in Iceland. This is illustrated in the identification of multiple complex disease loci and potentially involved alleles (**www.decode.com**). Also in the Decode project, most of the identified alleles represent rare, most probably high-impact alleles, and their significance at the population level remains unknown. Nevertheless, exploring the biochemical pathways behind rare, high-impact genes identified in special populations will without doubt contribute to our understanding of the molecular pathogenesis of these traits. The initial findings concerning specific alleles and their significance for the disease phenotype need to be followed by genetic analyses in other populations and epidemiological study samples for elucidating their general significance and their population attributable fraction.

Short Specialist Review

Allergy and asthma

Miriam F. Moffatt and William O.C. Cookson
University of Oxford, Oxford, UK

1. Introduction

Asthma is an inflammatory disease of the small airways of the lung. There is a modern epidemic of asthma, which now affects more than 10% of children in many westernized societies. The skin rash of infantile eczema (atopic dermatitis, AD) is also increasingly common in the developed world, affecting up to 15% of children in some countries. Asthma is present in 60% of children with severe AD, a significant proportion of which continue with problems into adult life. Both diseases are familial, and arise from the interaction between strong genetic and environmental factors (*see* Article 58, **Concept of complex trait genetics**, Volume 2).

AD, asthma, and hay fever are often considered to be part of a common syndrome of atopic diseases. The term "atopy" is variously used, but it most consistently refers to the presence of IgE-mediated skin test responses to common allergens. Atopic individuals are also typified by the presence of elevated levels of total and allergen-specific IgE in serum.

Childhood-onset asthma runs strongly in families, and studies of twins with asthma or AD show a heritability of approximately 60%. Consequently, many genome screens and candidate gene studies have been carried out to search for genetic effects on these illnesses.

2. The genetic basis of asthma

2.1. Genome screens

At least 11 full genome screens have been reported for asthma and its associated phenotypes (reviewed in (Cookson, 2003; Wills-Karp and Ewart, 2004)). These have identified 10 regions of linkage that were reproducible between screens and 4 regions that were statistically significant but not replicated by other groups (Cookson, 2003).

Asthma consistently shows linkage to the Major Histocompatibility Complex (MHC) (Cookson, 2002), in common with many other diseases, and linkage loci for asthma also overlap with loci for ankylosing spondylitis on chromosomes 1p31–36,

7p13, and 16q23; with type 1 diabetes on 1p32–34, 11q13, and 16q22–24; and with multiple sclerosis and rheumatoid arthritis on 17q22–24 (Cookson, 2002) (Figure 1).

These findings may mean that the susceptibility to different diseases arising from these loci is influenced by individual genes in various forms (alleles). Alternatively, as in the case of the MHC, disease susceptibility may be modified by physical clusters of genes that have a variety of effects on immune responses.

Three genome screens for AD have been carried out and have identified significant linkage to AD in four regions (reviewed in (Bowcock and Cookson, 2004)). These regions do not overlap with known regions of linkage to asthma but are closely coincident with psoriasis susceptibility loci (Bowcock and Cookson, 2004) (Figure 1). This suggests that particular genes or families of genes have general effects on immune reactions in the skin.

Wiskott–Aldrich syndrome, Hyper IgE syndrome, and Netherton's disease are Mendelian (single gene) disorders that show strong features of atopy.

Children with Netherton's disease consistently develop symptoms of atopic disease (hay fever, food allergy, urticaria, and asthma) and high levels of serum IgE. Mutations in the gene encoding a serine protease inhibitor known as SPINK5 or LEKTI was shown to be causing disease in these patients. Subsequent work has shown that common polymorphism in SPINK5 (particularly Glu420→Lys) modifies the risk of developing AD, asthma, and elevated serum IgE levels (Walley *et al*., 2001).

The SPINK5 protein contains 13 active protease inhibitor domains that provide a polyvalent action against multiple substrates. It is expressed in the outer epidermis, suggesting that AD and asthma may result from the failure to inhibit environmental proteases such as those that arise from bacteria or allergens.

Genetic linkage studies of AD and psoriasis have both highlighted the importance of chromosome 1q21, which contains the epidermal differentiation complex (EDC). Many of the EDC genes have shown increased expression in AD (Nomura *et al*., 2003) and in psoriasis (Nomura *et al*., 2003; Zhou *et al*., 2003).

Several gene families are present within the complex: these encode small proline-rich proteins (SPRRs), S100A calcium-binding proteins, and late envelope proteins (LEPs). The *SPRR* and *LEP* genes encode precursor proteins of the cornified cell envelope, whereas *S100* genes have antimicrobial and immune signaling functions. Expression of the EDC proteins occurs late during the maturation of epidermal cells, and, like SPINK5, EDC proteins are mainly localized just beneath the cornified envelope.

2.2. *Postionally cloned genes for asthma*

Four completely novel genes underlying asthma have been identified by positional cloning, from chromosomes 2q14 (*DPP10*) (Allen *et al*., 2003), 7p14 (*GPRA*) (Laitinen *et al*., 2004), 13q14 (*PHF11*) (Zhang *et al*., 2003), and 20p (*ADAM33*) (Van Eerdewegh *et al*., 2002). The functions and activities of these genes are as yet poorly understood, but they certainly do not fit into classical pathways of asthma pathogenesis.

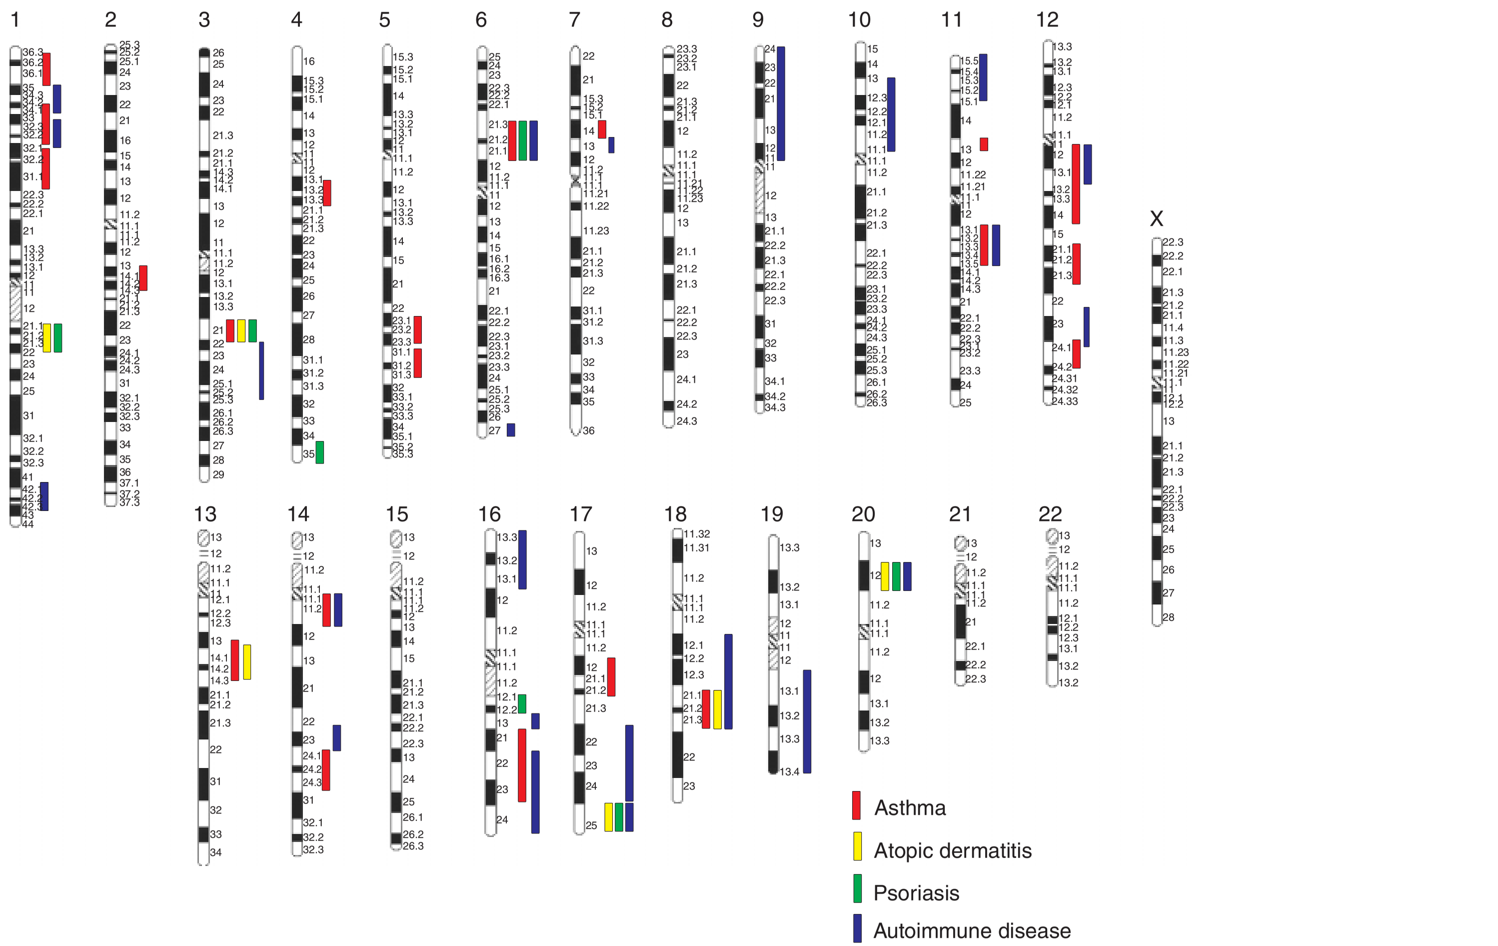

Figure 1 Genome screens for asthma, AD, and other immune disorders. The results are shown schematically, and only include the most significant linkages. The length of the bars indicates imprecision of localization. Clustering of disease susceptibility genes is found for the MHC on chromosome 6p21, and in several other genomic regions

ADAM33 is expressed in bronchial smooth muscle, and is thought to alter the hypertrophic response of bronchial smooth muscle to inflammation (a component of a process known as airway remodeling) (Van Eerdewegh *et al*., 2002). *PHF11* encodes a nuclear receptor that is part of a complex containing a histone methyl transferase (*SETDB2*), a regulator of HDAC (*RCBTB1*) and a nuclear transport molecule (*karyopherin α3*). *DPP10* encodes a prolyl dipeptidase, which may remove the terminal two peptides from certain inflammatory chemokines (Allen *et al*., 2003), and *GPRA* encodes an orphan G protein-coupled receptor named GPRA (G protein-coupled receptor for asthma susceptibility).

It is of interest that DPP10 and GPRA are both concentrated in the terminally differentiating bronchial epithelium. The homologous layer in the epidermis is the site of maximal expression of *SPINK5* and the genes of the EDC.

2.3. Candidate genes

2.3.1. The MHC

The MHC is the longest studied locus influencing atopy. It is well known that *HLA-DR* alleles restrict the IgE response to particular allergens, usually with a relative risk less than 2 (Young *et al*., 1994). In addition, the MHC Class II associated *TNF -308* promoter single nucleotide polymorphism (SNP) shows robust associations with asthma, independently of association to particular allergens (Moffatt and Cookson, 1997).

The MHC has, however, been little studied in individuals with AD. Genome screens do not show linkage of AD to the region, and no convincing associations with Human Leucocyte Antigen (HLA) Class I or Class II alleles have been established. Definitive studies are however lacking.

The ability to react to particular allergens has also been linked to the *TCR-α/δ* locus (but not *TCR-β*), and *HLA-DR* and *TCR-α/δ* alleles interact in the susceptibility to house dust mite allergens (Moffatt *et al*., 1997). The importance of γ/δ T-cells in dermal immunity suggests that the *TCR-α/δ* locus should also be explored in individuals with AD.

2.3.2. *FcϵRI-β* (chromosome 11q13)

Chromosome 11q13 was originally linked to atopy and was subsequently shown to contain the β-chain of the high-affinity receptor for IgE. Polymorphisms in *FcϵRI-β* are associated with asthma, allergy, bronchial hyper-responsiveness, and AD. These variations seem to be associated with severe atopic disease.

FcϵRI-β acts as an approximately sevenfold-amplifying element of the high-affinity IgE receptor response to activation and stabilizes the expression of the receptor on the mast cell surface. *FcϵRI-β* may therefore modify nonspecifically the strength of the response to allergens. Coding polymorphisms have been identified within the gene, but do not appear to alter its function. The actions of other polymorphisms within regulatory elements of the gene are currently under investigation.

2.3.3. The IL-4 cytokine cluster (chromosome 5q34)

The cytokine cluster on chromosome 5q34 contains many candidates that might influence atopic processes, including *IL-4*, *IL-13*, *GM-CSFH*, and *IL-9*. Polymorphisms in *IL-4* may be weakly associated with asthma, but a far stronger association has been established between *IL-13* polymorphisms and increased serum IgE levels, atopy, and asthma. The coding polymorphism Arg130->Gln seems to show the strongest effect (Graves *et al*., 2000).

These polymorphisms have not yet been explored for a role in AD. An association between *GM-CSF* and the severity of AD has been suggested but not yet confirmed.

IL4-Ra on chromosome 16 is a shared component of the receptor for both IL-4 and IL-13, and polymorphisms in this gene are also associated with asthma and atopy. It is of interest that different asthma-associated traits are associated with individual polymorphisms that affect splicing of IL4-Ra, illustrating the complexity of mechanisms that may vary the actions of a single gene.

2.3.4. Genes that interact with the microbial environment

CD14 is a receptor for bacterial lipopolysacchride (LPS, also known as endotoxin). This molecule is part of the innate immune response against bacterial infection. Polymorphism in the *CD14* gene is also associated with asthma, perhaps providing some of the structural explanation for the hygiene hypothesis. The intracellular pattern-recognition receptors *NOD1* and *NOD2* are also associated with asthma, through unknown mechanisms.

2.3.5. Pharmacogenetics and asthma

β-adrenergic drugs are the first line of treatment for asthma, and act through the β-adrenergic receptor (ADRB). Functional variants in *ADRB* modify the response of individual asthmatics to β-adrenergic therapy. A variant within the promoter of the 5-lipoxygenase gene predicts the response of asthmatics to antileukotriene therapy.

Short Specialist Review

Inflammation and inflammatory bowel disease

Christopher G. Mathew
King's College London, London, UK

1. Introduction

Inflammatory bowel disease (IBD) is associated with chronic inflammation of the gastrointestinal tract, and has two main forms, Crohn's disease (CD) and ulcerative colitis (UC). CD can affect any part of the intestine, with discontinuous, transmural lesions of the gut wall, whereas in UC, inflammation is confined to the colon and rectum, and lesions are continuous and superficial. The molecular basis of pathogenesis in IBD is not yet clear, but may involve persistent bacterial infection, a defective mucosal barrier, and an imbalance in the regulation of the intestinal immune response. There is strong evidence from both epidemiological and genetic studies for the existence of genetic determinants of susceptibility to IBD (Bouma and Strober, 2003; Mathew and Lewis, 2004).

2. The discovery of *NOD2* (*CARD15*)

Genetic linkage studies in IBD families identified a region of linkage on chromosome 16 (the *IBD1* locus), which was later shown by positional cloning to contain a gene called *NOD2* (now called *CARD15*) (Hugot *et al*., 2001). Mutations in *CARD15* were shown to be associated with susceptibility to CD (but not to UC), and the association was reported independently by two other groups (Hampe *et al*., 2001; Ogura *et al*., 2001), and has since been widely replicated. The predicted structure of the CARD15 protein (Figure 1) contains two caspase recruitment domains (CARDs), a central nucleotide-binding oligomerization domain, and 10 carboxy-terminal leucine-rich repeats (LRRs), which offers some clues as to its function (see below). Three common mutations have been described (Figure 1); a frameshift (L1007fs) that results in loss of the C-terminal LRR, a missense mutation in the LRR (G908 R), and a missense mutation between the nucleotide-binding domain and the LRR (R702 W). Numerous other rare variants have been detected, some of which may also affect function (Lesage *et al*., 2002). Heterozygosity for the mutations confers a two- to threefold increase in risk of CD, but in mutation homozygotes, the risk is increased by about 30-fold. The fact that only about 35–40% of CD patients have mutations in *CARD15* and that the mutations

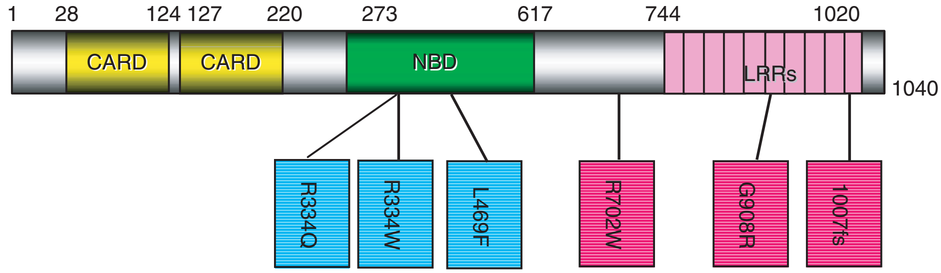

Figure 1 Predicted structure of the CARD15 protein and associated mutations. (CARD = caspase recruitment domain, NBD = nucleotide-binding domain, LRR = leucine-rich repeats). Crohn's disease mutations are in pink and Blau syndrome mutations in blue

are relatively common in the general population, shows that, as might be expected for a complex trait, they are neither necessary nor sufficient for the development of the disease. *CARD15* mutations have also been found in Blau syndrome, a rare autosomal dominant condition associated with early-onset granulomatous arthritis (Miceli-Richard *et al*., 2001). The Blau syndrome mutations are all located in the nucleotide-binding domain of CARD15, which may explain the differences in phenotype and penetrance.

3. *NOD2/CARD15* function

The identification of *NOD2/CARD15* was a very important discovery since it provided proof of the principle that positional cloning of susceptibility genes for complex diseases was possible. Knowledge of the identity of the encoded protein has also offered insight into a possible pathway to pathogenesis. The presence of LRRs suggested that, like the toll-like receptors (TLRs), it might be involved in the recognition of microbial components, and subsequent work showed that transfection of *CARD15* into HEK293 cells led to activation of NF-κB after stimulation with the peptidoglycan muramyl dipeptide (MDP) (Girardin *et al*., 2003; Inohara, Ogura *et al*., 2003). Patient-derived mutations of *CARD15* lead to a loss or reduction of MDP-mediated NF-κB activation in transfected and in primary cells (Ogura *et al*., 2001; Van Heel, *et al*., 2005; Li, Moran *et al*., 2004). This is puzzling, since CD is characterized by increased inflammation via an NF-κB-dependent T helper type (T_H1) response. Part of the resolution to this paradox may lie in the recent finding that *Card15*$^{-/-}$ mice have an enhanced TLR2-dependent response to peptidoglycan (Watanabe *et al*., 2004), which suggests that NOD2 downregulates the TLR2 response and that this control is deficient in Crohn's patients with *CARD15* mutations, leading to increased inflammation.

4. Other IBD genes

Numerous genetic linkage studies (reviewed in Mathew and Lewis, 2004) and a recent meta-analysis of genome scans (Van Heel, *et al*., 2004) have pointed to the existence of other susceptibility genes for IBD, including the MHC region

on chromosome 6p21 (see Table 1). Linkage around the cytokine gene cluster on chromosome 5q31-33 (*IBD5*) to CD led to the identification of a common risk haplotype over a region of 250 kb, which contained multiple SNPs that were in almost complete linkage disequilibrium (LD) with each other, and were strongly associated with CD (Rioux *et al*., 2001). The extensive LD did not permit the identification of a causative gene or mutation, but a recent report suggests that two variants in the *SLC22A4* and *SLC22A5* genes that encode organic cation transporters are the causative mutations (Peltekova *et al*., 2004). The missense substitution L503F in *SLC22A4* was associated with reduced carnitine uptake by the encoded OCTN1 transporter, and the −207G>C variant in *SLC22A5* (encoding OCTN2) occurs within a heat-shock transcription factor binding element that reduced transcriptional activation of a reporter gene by the mutated version of the promoter. It is argued that these variants may cause intestinal inflammation by, for example, defective metabolism of bacterial toxins (Peltekova *et al*., 2004), but the functional link between the OCTN transporters and CD is not immediately obvious. Confirmation of the role of these variants in the pathogenesis of Crohn's disease will require replication of their association with disease in the absence of the background 250 kb risk haplotype, and evidence of altered expression or activity of these genes in cells or tissues from CD patients.

Evidence for a third IBD susceptibility gene comes from a systematic search for association in a 40-cM region of linkage on chromosome 10. Transmission disequilibrium tests revealed strong association of a SNP with both CD and the broader IBD phenotype, with the signal being confined to a haplotype block of 85 kb across the *DLG5* gene at 10q23 (Stoll *et al*., 2004). Haplotype tagging SNPs were undertransmitted to IBD cases in a primary and a replication set of families, and a missense mutation (R30Q) was associated with disease in an independent sample of CD cases and controls, with an odds ratio of 1.6. *DLG5* is a member of the membrane-associated guanylate kinase gene family. It is expressed in the colon and intestinal epithelium (Stoll *et al*., 2004), and has been implicated in the regulation of cell growth and shape, and in the maintenance of epithelial cell integrity. Thus, it is proposed that genetic variants in *DLG5* may affect epithelial barrier function in the colon (Stoll *et al*., 2004). As with the *SLC22A4* and *SLC22A5* genes at the *IBD5* locus, independent replication of the genetic findings are needed, as well as functional studies to demonstrate the altered expression or activity of the DLG5 protein in cells or tissue from IBD patients.

5. Challenges for the future

What lessons can be drawn from the genetic findings at this point? First, the *CARD15* discovery emerged from a well-replicated linkage signal on chromosome 16, and, in the context of complex disorders, has a large effect size in mutation homozygotes. Also, since all three of the main susceptibility alleles arose on the same more ancient haplotype, common SNPs that tagged the haplotype all showed strong association with disease (Hugot *et al*., 2001). This discovery, impressive and important though it is, may therefore represent low-hanging fruit in the search for other genetic determinants of IBD. The challenge of identifying the causal

Table 1 Chromosomal regions showing significant/suggestive genome-wide evidence for linkage, from genome-wide linkage studies, and from two large consortium analyses (follow-up of chromosomes 12 and 16; IBD International Genetics Consortium, 2001), and a meta-analysis of 10 genome-wide linkage studies (Van Heel *et al*., 2004))

gene and variants in large regions of extensive LD is exemplified by the *IBD5* locus on chromosome 5q31, and is likely to complicate efforts to identify the IBD gene or genes in the region of strong LD around the MHC locus on chromosome 6p21. Also, if the effect sizes for other loci are relatively small, such as appears to be the case for *DLG5*, very large sample sizes may be required to confirm their existence. The availability of the immense database of SNPs has led to a large expansion in the number of reported associations in IBD, many of which have not been replicated. This is due in part to methodological problems in study design (Colhoun *et al*., 2003), and also due to the large numbers of tests being conducted. Theoretical and practical issues relating to multiple testing are about to escalate dramatically with the introduction of genome-wide screens for association with panels of 100 000–300 000 SNPs. Finally, in those instances in which strong and well-replicated evidence of association has been obtained, there will be the challenge of demonstrating credible functional links between putative susceptibility genes and pathogenesis.

If the prospect of these challenges seems daunting, many of them are common to other complex disorders, and the attempt to resolve them will be extremely interesting. A few more successes may have a major impact on our understanding of pathogenesis in IBD, and may provide novel targets for improvements in therapy.

Short Specialist Review

Hypertension genetics: under pressure

Fadi J. Charchar, Maciej Tomaszewski and Anna F. Dominiczak

University of Glasgow, Glasgow, UK

1. Introduction

Human essential hypertension (EH) is a typical example of a complex, multifactorial, and polygenic trait with a significant effect on public health. Although effective treatment is available, hypertension remains as a major risk factor for cardiovascular disease. Some mutations in genes responsible for the severe Mendelian forms of hypertension have been successfully identified (Lifton *et al*., 2001); in comparison, the search for the genes involved in EH (hypertension with unknown cause) has been less productive. The question that remains unanswered, as put forward by Luft (2004), is whether we can find such genes? The answer may lie in the methods and species that we use to discover these genes.

2. Genome-wide scans

The search for hypertension genes has mainly utilized genome screens or the candidate gene approach. The genome-wide scan is best defined as a search for quantitative trait loci across the entire genome. The quantitative trait locus (QTL) is a chromosomal region containing a gene or genes that may influence a trait of interest such as hypertension. A genome scan is designed primarily to detect causative regions without making presumptions to the physiological or pathological relevance of the genes in the region. Finding chromosomal regions containing one or more QTLs is usually the first step followed by saturation of the region with further markers or SNPs (single nucleotide polymorphisms) to grid-tighten the region (Mein *et al*., 2004) and to determine the causative gene(s). False-positive and false-negative results are, however, inevitable because the genotype–phenotype associations with QTLs are weaker than those observed with the more direct and severe Mendelian traits, and because nongenomic environmental factors can easily obscure any linkage. Additionally, even when the linkage is strong, the possibility remains that the cause of an increase or decrease in BP (blood pressure) is a linked but unrecognized genetic difference rather than the recognized polymorphic factor. Examples of this include publication of the two largest genome scans: the

Family Blood Pressure Programme (FBPP) and British Genetics of Hypertension (BRIGHT) study (Caulfield *et al*., 2003; Province *et al*., 2003). The FBPP showed no significant genome-wide linkage, except for a 2.96 LOD score on chromosome 1q for diastolic BP. In contrast, the BRIGHT study showed a locus for hypertension on chromosome 6q (LOD score of 3.21) that attained genome-wide significance and three further loci with suggestive evidence of linkage on chromosomes 2q, 5q, and 9q. The use of different markers, varying study designs, and characteristically broad linkage peaks resulting from by definition incorrect parameters in linkage analyses (the inheritance pattern of hypertension is not known) complicate the interpretation of the results of genome-wide scans.

3. Candidate gene studies

The candidate approach that associates EH with polymorphic variations in pathophysiologically relevant genes has not been successful in identification of consistent candidate(s) for further verification in functional studies. Consequently, despite high expectations, the contribution of most association studies to the understanding of hypertension and its genetic determinants has been modest. Lack of robust phenotyping, hidden population stratification or lack of relative power, has undoubtedly contributed to this. Recently, criteria have been suggested for the high-quality association studies (Ioannidis *et al*., 2001). These criteria would include really significant small *P*-values (e.g., surviving corrections for multiple testing), biologic plausibility, large sample size, functional significance, independent replication in several populations, and confirmation in family-based studies.

4. Rodent models

Analytical approaches using animal models have the potential to overcome some of the genetic and environmental complexities of human studies (Jacob and Kwitek, 2002). Inbred rat strains that display hypertension as an inherited trait have long been used as a means for identifying genes that can give rise to EH. These strains include spontaneously hypertensive rats (SHRs), stroke-prone spontaneously hypertensive rats (SHRSP), Dahl salt-sensitive rats, Sabra hypertensive rats, Milan, Lyon, fawn-hooded, and Prague hypertensive rats. To eliminate the variability arising from the heterogeneous genetic background of these animals, congenic and consomic rat strains have been developed and used to identify QTLs for hypertension. Congenic strains have a chromosomal region transferred to an inbred strain by backcrossing. Consomic strains have a single chromosome transferred to an inbred strain by backcrossing (McBride *et al*., 2004). Indeed, at least one QTL for BP has been identified on almost all chromosomes in the rat genome, confirming the complex and polygenic nature of the disease (Dominiczak *et al*., 2000). However, hundreds of genes can be present in the region encompassing the QTL(s) adding to the difficulty in identifying the causative gene(s).

While congenic mapping is an important approach, the narrowing of QTL regions to smaller than 200 kb and cloning of the gene responsible has only been achieved once (Cicila *et al*., 2001). Knockout, knockin, and transgenic models have yet to be utilized to help determine the contribution of individual genes within a congenic region to hypertension. Likewise, RNA interference is another method that can alter gene expression from a congenic region, and is yet to be used. Development of these approaches and others in a targeted systematic way will be required to understand the role of individual genes within congenic intervals. We also predict that more than one model or species will be needed to verify genes. Indeed, evolutionary studies may come to the rescue here, since real polymorphisms in genes that are highly conserved between more than one species may be the real culprits in EH. On the controversial side, it may be that the rodent model will only be truly valuable for further physiological interrogation of human candidate genes for EH (as in pharmacological studies) rather than the discovery of genes. However, findings from other diseases and lessons learned from other model organisms show that this is not the case.

5. Transcript profiles

Recent advances in molecular biology and technology have made it possible to examine the expression levels of virtually all genes (mRNA or proteins). As the tools for gene expression profiling using microarray have become more widely available, the number of investigators applying this technology in hypertension research, as in other fields of biomedical research, has grown rapidly, in particular using animal models. A combination of congenic mapping and transcription profiling was successfully used to implicate glutathione S-transferase μ-type 1 in hypertension (McBride *et al*., 2003). In humans, microarrays obviously require cells or tissues for analysis. A direct application to the genetics of human hypertension requires biopsies of samples from relevant tissues. Such approaches are technically feasible and will undoubtedly soon be applied to EH.

6. How diverse is the genetic background of hypertension?

It is clear from data published so far in both human and animal models of hypertension that hypertension is complex polygenic disorder. There is no real consensus on the number or the actual genes involved. The lower statistical power of linkage screens means that the number of human hypertension loci is likely to be much more than what was thought previously by researchers in the field (even in the order of tens of genes suggest Mein *et al*., 2004). Recently reported genome screens suggest that there are no genes with a major effect. Mein *et al*. (2004) remark that “we are looking for many genes with a genotype relative risk of 1.2–1.5”. In addition, there is still no evidence that BP genes identified in rodents will be the same as the causative genes in humans. The present challenge is to confirm linkage peaks (in both human and the rat) and identify disease predisposing variants using new resources that are becoming available, for example, the SNP haplotyping,

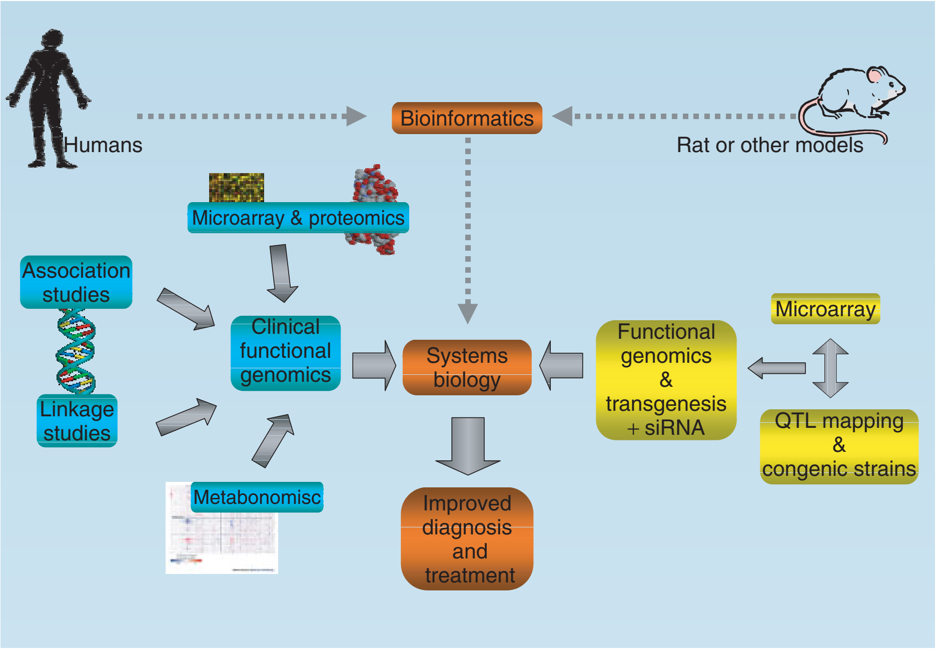

Figure 1 There is a need to improve treatment and diagnosis of EH in humans. Here we present a feasible schema on the future direction of hypertension research to meet this challenge. In humans, association and linkage studies, microarrays, proteomics, and metabonomics can be used to identify molecular targets that must be tested in both functional genomic and clinical experiments. In the animal models, the use of QTL and congenic mapping can be used to identify genes that can be tested by transgenesis and functional experiments. To identify disease predisposing variants, we will rely on comparative biology with the aid of bioinformatics between humans and animal models. Robust candidates can then be studied using systems biology in animal models. Ultimately, the development of better diagnosis and treatment from pharmacogenetics will lead to the health benefits

microarrays, bioinformatics, proteomics, and metabonomics (Figure 1). Future efforts to find associations in humans may rely upon dense collections of SNP screens to identify hypertension susceptibility loci. But these need to have enough power to detect genes with a lower relative risk. Factors that are yet to be determined fully in such studies are SNP selection, analysis methods, study size, heterogeneity in sample collections, linkage disequilibrium, and haplotype tagging. It may be too early or pessimistic to say that “genetics might never contribute to the diagnosis of EH” (Harrap, 2003) simply because its cause is too complex. It is easy to forget that our current explosion of genetic and genomic tools is only recent, and whether EH is caused by common or rare variants, the plummeting cost for these emerging technologies will have an impact in the future.

7. Future challenges

Although major advances in our understanding of the mechanism of disease development and in the treatment of EH have been achieved over the past few decades,

substantial gaps in our genetic knowledge remain. Bringing together scientists representing multiple disciplines and expertise will give us the opportunity to narrow these gaps of knowledge in the future. We predict that the postgenome era, with its ability to study functions and interactions of all the genes in the genome, including their interactions with environmental factors, will bring improved understanding of EH as a complex trait. Furthermore, we predict that the traditional genetic paradigm with its central dogma of gene to function will increasingly dominate mechanistic studies in hypertension in both animal models and humans (Figure 1). The increased prevalence of hypertensive complications, high costs of antihypertensive therapy along with its social implications in both the developed and developing world (Whitworth, 2003), puts researchers "under pressure" to dissect the genetic pathophysiology of EH. Ultimately, the success of the genetics of EH will be best measured by the progress achieved in the better understanding and treatment of EH in all patients over the next few years.

Acknowledgments

This study was funded jointly by a British Heart Foundation Programme Grant (98001) and the Wellcome Trust Cardiovascular Functional Genomics Initiative (066780).

Short Specialist Review

Genetics of cognitive disorders

Brett S. Abrahams and Daniel H. Geschwind
David Geffen School of Medicine, UCLA, Los Angeles, CA, USA

1. Cognition and genetic modulation

Disorders of cognition impair mental processes mediating awareness, perception, reasoning, or judgment, and consequently interfere with thinking. Although interindividual differences in human cognition are easily observed, little is known about the genetic factors underlying such phenotypic variation. Phenotypes associated with cognition range from what are currently considered the more measurable, such as language and memory, to spatial and social abilities, which have been less aptly defined. Progress in understanding the genetics of cognition and cognitive disorders necessarily relies on progress in understanding brain-behavior relationships, a discipline that is still in its infancy. We are likely to gain significant insight into the molecular basis of normal variation in human performance from the study of Mendelian and complex genetic disorders of cognition.

2. Brain structure differences are heritable

One important factor to consider is that genetic factors influence cognitive phenotypes only indirectly, through modulation of brain structure and function. At the same time, heritability for differences in brain structure is high (Thompson *et al*., 2001; Pfefferbaum *et al*., 2004), with estimates ranging from 0.65 to 0.95 (Thompson *et al*., 2001; Geschwind *et al*., 2002). Heritability for differences in brain structure is similar to that for common neuropsychiatric disorders involving the development of cognition and behavior, including dyslexia (0.4–0.6; DeFries and Alarcon, 1996; Wadsworth *et al*., 2000), attention-deficit hyperactivity disorder (0.6–0.9; Gjone *et al*., 1996; Levy *et al*., 1997), and autism (0.6–0.9; Folstein and Rutter, 1988; Bailey *et al*., 1995). A more complete understanding of the alterations in brain structure that underlie these disorders will provide important phenotypes that are directly amenable to genetic analyses. One example of recent progress in our understanding of genetic modulation of brain structure comes from the work linking a common variant within brain-derived neurotrophic factor (BDNF) to both differences in hippocampal and prefrontal gray matter volumes, as well as performance on an episodic memory task in normal subjects (Egan *et al*., 2003; Hariri *et al*., 2003; Pezawas *et al*., 2004). It will likely be worthwhile to explore the extent to which variation at *BDNF* influences diseases of memory.

3. Spearman's "g": a unitary intelligence?

Spearman's "g" parallels the concept of IQ and attempts to capture the finding that individuals who do well on some types of cognitive tests generally do well on others. Twin data suggest that heritability of g varies as a function of age, with estimates of 40% in childhood and upward of 60% later on in life (McClearn *et al*., 1997; Plomin and Craig, 1997; Alarcon *et al*., 1998; Alarcon *et al*., 2005). Although initially a purely theoretical construct, recent work has begun to define the structures and circuitry that may underlie interindividual differences in general cognitive performance as measured by standardized tests. Such work suggests that structural variation within the frontal cortex, specifically the dorsolateral prefrontal cortex and medial frontal gyrus, are important modulators of g-related tasks (Duncan *et al*., 2000; Thompson *et al*., 2001). The involvement of these well-studied frontal regions suggests that g may be measuring some form of executive function and working memory, rather than general intelligence. That g is heritable is likely to provide one window, albeit imprecise from the standpoint of cognitive neuroscience, to link brain, genes, and behavior.

4. Disease genes and normal variation in performance

A large body of work now demonstrates that loss-of-function mutations in a variety of brain-expressed genes can give rise to profound and relatively generalized cognitive dysfunction (Ross and Walsh, 2001). Less clear, however, is whether differences in cognition between normal individuals may be due to common variants within these same genes (Plomin and Rutter, 1998), one paradigm driving research in this area. Similarly, it remains to be seen whether genetic variation underlying disease-related endophenotypes may help explain corresponding phenotypic differences within the normal population. To some extent, both will depend on whether particular clinical entities are qualitatively different from the corresponding "normal state" or, alternatively, an extreme within the normal distribution. At present, neuropsychiatric disease status is based on practical definitions of function within society, representing an arbitrary cutoff, rather than a qualitatively distinct state. Finding ways to identify and measure heritable endophenotypes rather than using clinically defined disease status, which may have little direct relationship to genetic factors, represents one of the most promising avenues for defining the genetic basis of cognitive disorders.

5. Autism and broader phenotype definitions

Along these lines, the study of individuals with autism may increase our understanding of several different aspects of cognition and behavior, as it is defined by deficits in three major domains: language, social interaction, and repetitive restrictive behavior (Folstein and Rosen-Sheidley, 2001). Although some monogenic syndromes (Tuberous Sclerosis, Fragile X, Joubert, and Rett Syndrome) show phenotypic overlap or increased co-occurrence with autism (Holroyd *et al*., 1991; Feinstein and Reiss, 1998; Ozonoff *et al*., 1999; Mount *et al*., 2003; Wiznitzer, 2004),

Table 1 Gene/locus findings for language-related disorders including autism, dyslexia, and specific language impairment

Disorder	(Endo)phenotypes considered[a]	Locus[b] (References)
Autism	Delayed onset of phrase speech	2q (Buxbaum *et al*., 2001; Shao *et al*., 2002)
	Autism-spectrum disorders	3q25-27 (Auranen *et al*., 2002; Auranen *et al*., 2003)
	Autism diagnosis only	7q (IMGSA-Consortium, 1998; IMGSA-Consortium, 2001)
	Language, repetitive behaviors	7q (Alarcon *et al*., 2002; Alarcon *et al*., 2005)
	Autism diagnosis only	7q36 – *Engrailed 2* gene (Petit *et al*., 1995; Gharani *et al*., 2004; also see Zhong *et al*., 2003)
	Autism diagnosis only	15q11-q13 (Baker *et al*., 1994; Cook *et al*., 1997; Cook *et al*., 1998; Schroer *et al*., 1998; Nurmi *et al*., 2003; also see Salmon *et al*., 1999)
	Insistence on sameness	15q11-q13 (Shao *et al*., 2002)
	Autism diagnosis only	15q11-q13 – *GABA* receptor genes (Martin *et al*., 2000; Menold *et al*., 2001; Buxbaum *et al*., 2002; also see Maestrini *et al*., 1999)
	Autism diagnosis only	Xp22 – *Neuroligin4* gene – (Thomas *et al*., 1999; Jamain *et al*., 2003; also see Gauthier *et al*., 2004; Laumonnier *et al*., 2004; Vincent *et al*., 2004)
	Autism diagnosis only	Xq13 – *Neuroligin3* gene – (Jamain *et al*., 2003; also see Gauthier *et al*., 2004; Vincent *et al*., 2004)
Dyslexia	Dyslexia diagnosis only	1p34-36 (Rabin *et al*., 1993; Grigorenko *et al*., 2001)
	Spelling performance	1p34-36 (Tzenova *et al*., 2004)
	Dyslexia diagnosis only	2p11 (Kaminen *et al*., 2003; Peyrard-Janvid *et al*., 2004)
	Dyslexia diagnosis only	2p15-16 (Fagerheim *et al*., 1999; Petryshen *et al*., 2002)
	Spelling performance	2p15-16 (Petryshen *et al*., 2002)
	Reading disability measures	6p21 (Cardon *et al*., 1994; Grigorenko *et al*., 1997; Fisher *et al*., 1999; Gayan *et al*., 1999; Grigorenko *et al*., 2000; Kaplan *et al*., 2002; Turic *et al*., 2003)
	Dyslexia diagnosis only	15q21 – *DYX1C1* gene – (Taipale *et al*., 2003; also see Scerri *et al*., 2004)
	Reading disability measures	18p11.2 (Fisher *et al*., 2002)
Other language impairment	Specific language impairment (language and reading scores)	16q (SLI-Consortium, 2002; SLI-Consortium, 2004)
	Specific language impairment (low standard language scores)	19q (SLI-Consortium, 2002; SLI-Consortium, 2004)
	Speech and language disorder with orofacial dyspraxia	7q31 – *Forkhead 2* gene (Fisher *et al*., 1998; Lai *et al*., 2001; Liegeois *et al*., 2003; see O'Brien *et al*., 2003 for evidence suggesting region may also be involved in specific language impairment)

[a]Endophenotypes considered but without significant linkage/association are not included.
[b]Obtained by linkage or association.

the genetics of idiopathic, nonsyndromic autism are complex and heterogeneous (see Table 1). Quantitative analysis of language performance amongst patients points to the presence of modulation of language performance by specific genetic factors (Alarcon *et al*., 2002; Alarcon *et al*., 2005). Further support for the use of quantitative methods for analysis of abnormal social interaction in autistic subjects

comes from data that suggests that such behavior may simply represent an extreme within the normal range of phenotypic variation in social cognition and behavior (Constantino and Todd, 2003). Despite some work suggesting reduced heterogeneity after clustering by repetitive behavior presentation (Buxbaum *et al*., 2004), it is not yet clear whether such behaviors in patients similarly represent part of the normal continuum, and if so, whether when observed in isolation such abnormalities might present as obsessive compulsive disorder. The extent to which domain-specific measures, as compared to a categorical diagnosis of autism, may increase power for gene identification remains to be determined, but appears promising. Following the observation that males are at increased risk for autism, stratification of families into those containing males only has also proven to be a powerful way to reduce heterogeneity (Stone *et al*., 2004; Cantor *et al*., 2005). Such an approach may be broadly applicable to other neurodevelopmental disorders with sex-dependent differences in incidence. Despite the clear utility of quantitative approaches and population stratification, important advances are also being made from the joint consideration of broadly related, yet clinically distinct, autism-spectrum disorders (Auranen *et al*., 2002; Auranen *et al*., 2003). Linkage to 3q25-27, after scoring family members with any of infantile autism, Asperger syndrome, or developmental dysphasia as affected, suggests that at least a subset of phenotypes shared amongst autism-spectrum disorders may possess a common genetic etiology. This again highlights the limited utility of categorical clinical definitions of complex neuropsychiatric disease in genetic studies. All of these methodologies will likely profit from an increased understanding of the genetic basis of developmental factors fundamental to human cognition and language, such as brain asymmetry (Geschwind, 1979; Geschwind and Miller, 2001; Geschwind *et al*., 2002; Herbert *et al*., 2004; Herbert *et al*., 2005). While some of these genetic influences may lie on the sex chromosomes (Skuse *et al*., 1997), most are likely to be autosomal (Stone *et al*., 2004).

6. Dissociating cognitive and behavioral abnormalities

Cognition and behavior can be strongly linked even within single-gene disorders. A single gene may effect the development of multiple brain structures, a single brain structure may be involved in several distinct cognitive and behavioral functions, or a single gene may affect a process, such as neurotransmission, that is widely distributed in different brain circuits that serve distinct functions. A good example of this linkage is observed in a rare Dutch family in which males hemizygous for a null allele of the X-linked Monoamine Oxidase A (*MAOA*) gene show cognitive impairment and violent behavior (Brunner *et al*., 1993). Although converging lines of evidence (Cases *et al*., 1995; Caspi *et al*., 2002) strongly support the idea that allelic variation at *MAOA* does in fact modulate behavior, it is not yet clear whether the extent to which the behavior abnormalities are secondary to cognitive dysfunction, or simply reflect dysfunction in multiple distributed brain circuits. At the same time, the existence of disorders in which cognitive processes are impaired but behavior remains intact (Fisher and DeFries, 2002; Good *et al*., 2003) demonstrates that certain elements of behavior and cognition can be clearly dissociated.

In a parallel vein, it is important to consider that although "mental retardation" or "generalized cognitive dysfunction" may be useful clinical conceptualizations, each is insufficiently precise for a detailed understanding of how genetic variation influences brain structure, and secondarily, cognitive function. Salient examples of this fact are found in the myriad of mental retardation syndromes, in which subjects have the same low IQ, but show dramatic differences in specific cognitive or behavioral domains (Bellugi *et al*., 1999; Folstein and Rosen-Sheidley, 2001; Whittington *et al*., 2004). Similarly, cognitive impairment in some domains may accompany real strengths in others, as is the case in certain neurodevelopmental syndromes (Plaisted *et al*., 1998; Happe, 1999; Heaton, 2003), dementias (Miller *et al*., 2000; Miller and Hou, 2004), or more circumscribed impairments such as developmental dyslexia (Nation, 1999; Richman and Wood, 2002). These cases emphasize the need for broad and detailed neurocognitive and behavioral assessment to carefully delineate specific phenotypes that comprise different cognitive disorders.

7. Successes from the study of language disorders

Disorders of language represent one area where cognitive deficits are typically distinct from disturbances in behavior. Additionally, language is a uniquely human cognitive ability that while genetically complex, can be broken down into underlying cognitive and linguistic components. Also, because a good deal is known about the structural basis of language in the brain (Galaburda *et al*., 1978; Geschwind, 1979), the interpretation of how allelic variation modulates specific structure-function relationships is facilitated. Independent genome-wide scans for developmental dyslexia, or specific reading impairment, has highlighted multiple genomic loci (see Table 1). Similarly, the study of specific language impairment, defined as difficulty in the acquisition of language skills amongst individuals with normal intelligence and access to education, supports the involvement of at least two loci (SLI-Consortium, 2002; SLI-Consortium, 2004). While no gene for either dyslexia or specific language impairment has been conclusively identified, a translocation disrupting *DYX1C1* segregated with dyslexia in one family, and two common variants were overrepresented amongst other affected individuals (Taipale *et al*., 2003). However, the importance of this gene in other dyslexic populations remains unclear (Scerri *et al*., 2004), highlighting the difficulties of replication in complex and heterogeneous disorders of cognition (*see* Article 57, **Genetics of complex diseases: lessons from type 2 diabetes**, Volume 2 and Article 60, **Population selection in complex disease gene mapping**, Volume 2).

The only gene clearly linked to human speech and language is *FOXP2,* identified by the study of a family segregating a rare Mendelian disorder involving speech dyspraxia, language and grammatical impairment, and other aspects of cognitive dysfunction (Lai *et al*., 2001). Interestingly, subsequent evolutionary analysis of *FOXP2* shows positive selection in humans, supporting the notion that it has been adapted for language-related cognitive specialization in humans (Enard *et al*., 2002a). At the same time, conserved *FOXP2* expression between birds and humans may suggest a more general role in vocal-motor learning (Teramitsu *et al*., 2004),

emphasizing the substantial complexity of even single-gene disorders of cognition and the utility of animal models and evolutionary comparisons. Other monogenic syndromes that are associated with language impairment, for example, Klinefelter Syndrome, Floating-Harbor Syndrome, and Neurofibromatosis type 1 (Robinson *et al*., 1988; Hofman *et al*., 1994; Geschwind *et al*., 2000), may also prove useful in our understanding of language development and dysfunction.

8. Promise for the future

As intriguing as all these data are, few would argue that they represent only a glimpse of what is likely to be uncovered in the next 20 years. Widespread application of emerging genomic approaches (Karsten and Geschwind, 2002; Geschwind, 2003), and the integration of phenotype data with copy number polymorphisms (Sebat *et al*., 2004) and single-nucleotide variation (Sachidanandam *et al*., 2001; Gabriel *et al*., 2002) will provide a more comprehensive understanding of the molecular biology underlying the regulation of human cognition. Efforts to limit false-positives (Ioannidis *et al*., 2001), and at the same time allow for multilocus, gene–gene and gene–environment interactions will be valuable. Because neither the human genome nor human environment is amenable to experimental manipulation, promising associations must be followed up in experimental systems. Although some aspects of cognition may be difficult to translate to the laboratory, many others will benefit from cellular or in vivo assays. Interspecies comparisons, particularly those calling on multiple primate species (Enard *et al*., 2002b; Caceres *et al*., 2003; Khaitovich *et al*., 2004; Preuss *et al*., 2004), or in the case of speech, vocal learners such as the songbird (Teramitsu *et al*., 2004) will add value to these endeavors. Such work will not only provide important insights into human disease but may also provide empirical answers to fundamental and long-standing philosophical questions that motivate much of the research in this area.

Acknowledgments

Work on autism and the genetics of human cognitive specializations in the Geschwind laboratory is supported by grants from the NIH (NIMH and NINDS) and the James S. McDonnell Foundation. We gratefully acknowledge numerous insights we have gained from a number of ongoing collaborations and our collaborators.

Short Specialist Review

Complexity of cancer as a genetic disease

Tea Vallenius and Tomi P. Mäkelä
University of Helsinki, Helsinki, Finland

1. Cancer is a complex genetic disease

Although cancer is clearly a genetic disease, only a small fraction of cancer is hereditary, and instead the majority of genetic alterations accumulate during disease progression. These somatic mutations are caused by DNA-damaging agents either arising from endogenous metabolic sources or external harmful agents. Occasionally, and fortunately rarely, mutations occur in an oncogene or a tumor-suppressor gene facilitating continued growth and viability of cells, leading to clonal expansion. Accumulation of subsequent mutations can provide the cells with further growth-promoting characteristics, and thus progression of tumorigenesis (Hanahan and Weinberg, 2000), which is generally believed to require several independent genetic insults (Hahn and Weinberg, 2002). Another classic hallmark of cancer cells are the frequent abnormalities in chromosome numbers (aneuploidy). Both the mechanisms leading to aneuploidy, and the role of aneuploidy in tumor progression remain debated issues. One of the models has presumed that aneuploidy simply reflects a general increased propensity of tumor cells to acquire mutations (mutator phenotype). Interestingly, it was recently noted that mutations in the *CDC4* gene are sufficient to lead to aneuploidy of colon cancer cells, suggesting that aneuploidy could be the result of mutations in specific genes (Rajagopalan and Lengauer, 2004). On the basis of the current knowledge of signaling pathways targeted in cancer, it is clear that a number of significant pathways and their interplay are poorly understood. The increasing number of tools enabling us to analyze cancer cells and tissues from a systems level viewpoint has set the stage for important new discoveries in this field. From the viewpoint of treating cancer, the most important question is how these results translate to therapy.

2. Targeted cancer therapy

Identification of specific oncogenic lesions common in some forms of cancer has spurred development of drugs targeted against these to support or even replace traditional chemo- and radiotherapies. The first success was the discovery of a

selective tyrosine kinase inhibitor imatinib mesylate (STI-571, Gleevec) in the treatment of chronic myeloid leukemia (CML) (Druker *et al*., 2001). Although imatinib was initially used in CML as an inhibitor of the BCR-ABL fusion protein, subsequently, it has been shown to inhibit additionally c-kit and PDGFR in a variety of tumor types (Druker, 2004). These success stories have motivated attempts to identify compounds that selectively block the activity of certain critical molecule in tumor cells, and hundreds of potential drugs, both specific small molecule inhibitors as well as monoclonal antibodies, are under different stages of development (**www.nci.nih.gov/clinicaltrials**). One very interesting class is epidermal growth factor receptor inhibitors gefitinib (Iressa) and erlotinib (Tarceva), which block the signal transduction pathways implicated in cancer cell growth and survival (Ross *et al*., 2004). Gefitinib trials in non-small-cell lung cancer (NSCLC) were initially disappointing due to a large variation seen in its ability to reduce lung carcinomas. However, more recent studies indicate that patients who respond to gefitinib treatment carry a mutation in a kinase domain of EGFR, pinpointing the need for diagnostic tools to select patients who will benefit from this treatment (Lynch *et al*., 2004; Paez *et al*., 2004).

These encouraging results reflect a changing trend in cancer therapy. At the same time, the trials with these drugs have been educating in the way of understanding the possibilities of killing cancer. Although there is a wealth body of evidence indicating that cancer is caused by the accumulation of mutations, the clinical responses attained from first targeted kinase inhibitors suggest that at least certain tumors are highly dependent on activation of a single kinase. This in turn increases the hope that other tumor types might be dependent on other kinases, which could be used in developing cancer-specific drugs. Obviously, this means that it will be fundamental to identify kinases or other molecules and their signaling mechanisms that maintain the progression of different tumors. To this end, integrated research data is required from different large-scale analysis including transcriptomics, and proteomics (Figure 1). In addition to the rapidly increasing expression and proteomics profiling data, it is important to identify specific gene mutations as demonstrated by, for example, the NSCLC and GIST experiences described above; mutations in specific genes are more indicative than changes in expression levels (Medeiros *et al*., 2004; Paez *et al*., 2004). Furthermore, the rapidly emerging field of biomarker identification through mass spectrometry and the ability to analyze posttranslational modifications in large scale provide information that should be integrated in the drug target discovery process.

Although clinical experience on targeted therapies is still in its early days, it is already known that relapses occur at some frequency, and, for example, in CML more frequently with patients having more advanced stages of disease (Gorre *et al*., 2001). In some cases of CML, the relapse is due to clonal expansion of a cell that acquires additional mutations in the targeted BCR-ABL kinase leading to reactivation of the damaged signaling pathway. It is also important to note that in the clinical setting, new promising candidate drugs are generally tested initially in patients with end-stage disease and usually as an added component to a treatment regimen of one or more traditional anticancer drugs. Results might be both better and easier to interpret if trials could be performed at earlier disease stages. In this

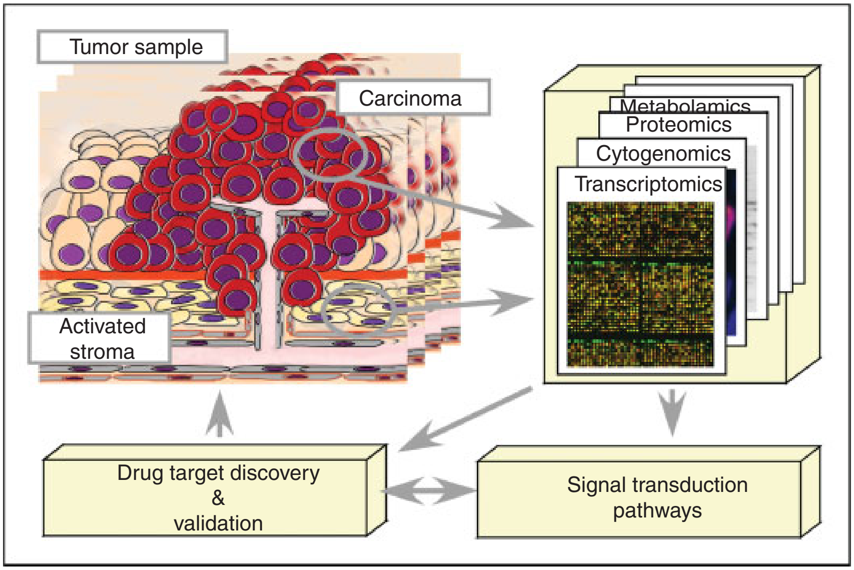

Figure 1 Integrated research data from different large-scale analyses is likely to speed up the understanding of signal transduction pathways leading to cancer and the development of cancer-specific drugs

respect, one current limitation to study drug effects is appropriate in vivo tumor models, particularly mouse models mimicking human cancer.

3. Stromal cells in tumors as therapy targets

Along with studies trying to identify the deregulated molecular circuits leading to the growth of neoplastic cells, a lot of attention has been recently focused on the interplay between neoplastic epithelial cells and the surrounding normal cells (Bhowmick *et al*., 2004b; Mueller and Fusenig, 2004). The neoplastic epithelial cells evolve ways in which to utilize several types of normal cells, for example, through production of growth factors, proteases, and so on. The ensuing stromal reaction is characterized by the presence of activated fibroblasts, proliferating blood vessel cells, altered extracellular matrix, and inflammatory response, all of which help the tumor to grow further and finally metastasize (Mueller and Fusenig, 2004). A dramatic example of this was provided by the observation that lack of TGF-signaling in fibroblasts resulted in epithelial neoplasia (Bhowmick *et al*., 2004a). This and other studies have led to the proposal that modified tumor contributes to tumor formation and progression (Bhowmick *et al*., 2004b). These types of observations are increasing interest in attempting to target the supporting cells of the carcinoma with therapy. On this line, the established strategy is antiangiogenic therapy, where endothelial cells growing into the tumors and providing tumor vasculature are targeted. Several antiangiogenic compounds are under development of which bevacizumab (Avastin) was the first to be approved for patients having

metastatic colorectal cancer (Ross *et al*., 2004). Bevacizumab is a monoclonal antibody neutralizing VEGF, which in turn loses it ability to activate its receptor on endothelial cells, and thus prevents the formation of new blood vessels. Another potential therapeutic strategy is to inhibit inflammatory cells and cytokines by nonsteroidal anti-inflammatory drugs, such as COX-2 inhibitors (Mueller and Fusenig, 2004). The future will show how these compounds survive in anticancer therapy, but it has been speculated that one benefit to target stroma is that these cells are genetically more stable than epithelial neoplastic cells and thus less subjected to developing drug resistance (Mueller and Fusenig, 2004). However, it is clear that further investigation into the tissue-specific interactions between neoplastic and stromal cells will be an essential component of rational drug development.

4. Conclusions

The recent significant achievements in cancer research accompanied by the available postgenomic era tools offer a lot of optimism to understand the enormous heterogeneity in genetic alterations and their implications in cancer. This does not mean that the primary therapy for a solid tumor is surgery when possible or that chemo- and radiotherapy remain as major forms of cancer therapy. However, several recent breakthroughs in the targeted cancer therapy indicate that they have arrived to stay as important tools in treating cancer patients. During the next several years, numerous new, targeted drug products will be introduced accompanied by diagnostic assays designed to identify right patients for each compound.

Short Specialist Review

The mitochondrial genome

Douglas C. Wallace
University of California, Irvine, CA, USA

1. The nature of the mitochondrial genome

The mitochondria are semiautonomous bacteria that reside within the cytoplasm of virtually all eukaryotic cells. These bacteria formed a symbiotic relationship with a nucleated host cell over 2 billion years ago. At the time of the symbiosis, the bacterial (mitochondrial) DNA contained all of the genes necessary for a free-living organism. However, over time, most of the genes in the mtDNA were transferred to the host cell's nuclear DNA (nDNA). Consequently, today the mitochondrial genome is distributed between the mtDNA and the nDNA.

The mtDNAs of humans and mammals retain the same genes. These include the small (12 S) and large (16 S) ribosomal RNAs (rRNA), the 22 transfer RNAs (tRNAs) necessary to translate the modified mitochondrial genetic code, and 13 proteins. The 13 proteins are all key components of the mitochondrial energy generating pathway oxidative phosphorylation (OXPHOS), and include seven (ND1, ND2, ND3, ND4L, ND4, ND5, ND6) of the approximately 46 polypeptides of OXPHOS complex I, one (cytochrome b, cytb) of the 11 proteins of complex III, three (COI, COII, COIII) of the 13 proteins of complex IV, and two (ATP6, ATP8) of the approximately 16 proteins of complex V. All of the remaining proteins of the mitochondrial genome, currently estimated to be about 1500 and including those for the polymerases, ribosomal proteins, structural proteins, and enzymes, are now located in the nucleus (Wallace and Lott, 2002).

While the nDNA-encoded mitochondrial genes are inherited, replicated, transcribed, and translated like other nDNA genes, the biology and genetics of the mtDNA genes is totally different. Consequently, the genetics of the mitochondrion is unique and complex.

The human mtDNA is a circular molecule of approximately 16 569 nucleotide pairs (nps) (Figure 1). In addition to the 37 structural genes, the mtDNA encompasses an approximately 1000-np control region (CR).

2. Mitochondrial function

Mitochondria generate energy by burning hydrogen derived from carbohydrates and fats with oxygen to generate water (H_2O) (Wallace and Lott, 2002) (Figure 2).

As a toxic by-product of OXPHOS, the mitochondria generate most of the reactive oxygen species (ROS or oxygen radicals) of eukaryotic cells. This results

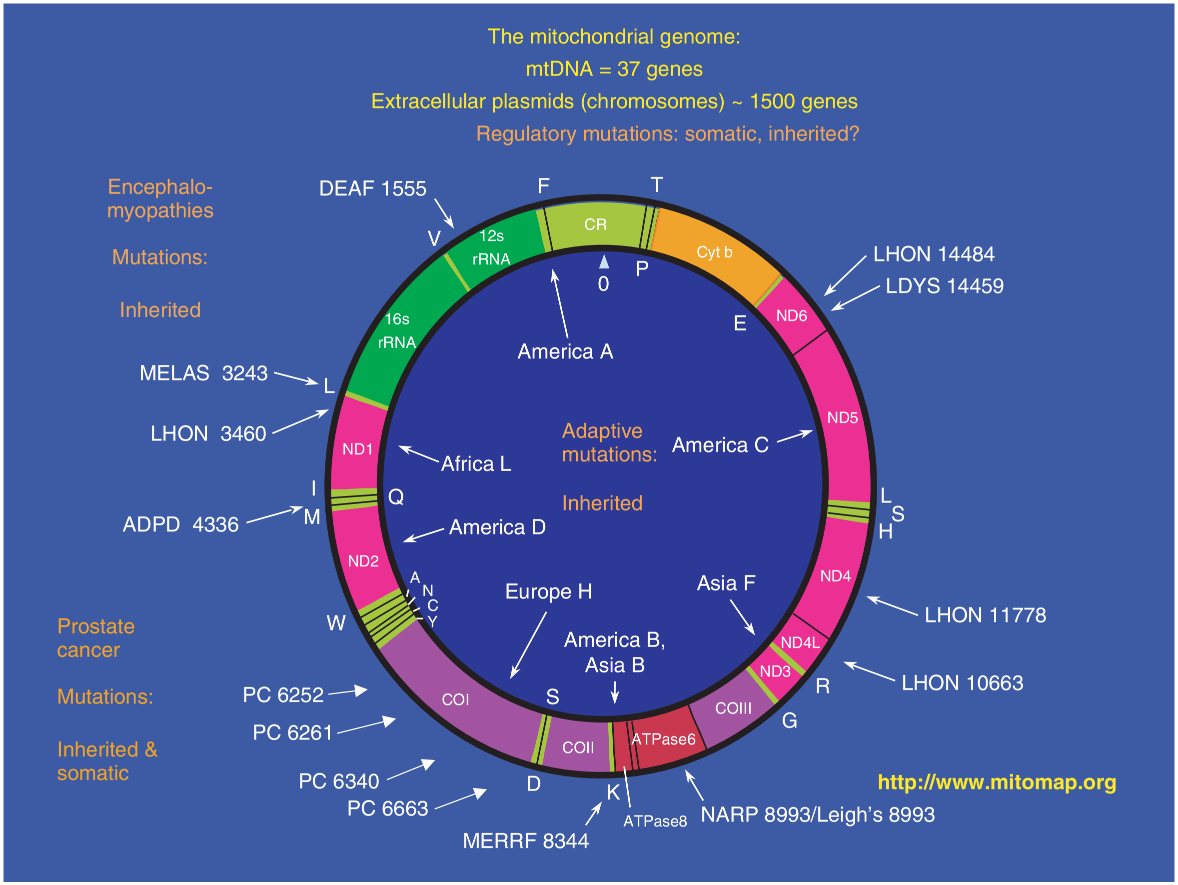

Figure 1 Human mitochondrial DNA Map. D-loop = control region. Letters around the outside perimeter indicate cognate amino acids of the tRNA genes. Other gene symbols are defined in the text. Arrows followed by continental names and associated letters on the inside of the circle indicate the position of defining polymorphisms of selected region-specific mtDNA lineages. Arrows associated with abbreviations followed by numbers around the outside of the circle indicate representative pathogenic mutations, the number being the nucleotide position of the mutation. The abbreviations are DEAF = deafness; MELAS = mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes; LHON = Leber's hereditary optic neuropathy; ADPD = Alzheimer's and Parkinson's disease; MERRF = myoclonic epilepsy and ragged red fiber disease; NARP = neurogenic muscle weakness, ataxia, retinitis pigmentosum; LDYS = LHON + dystonia

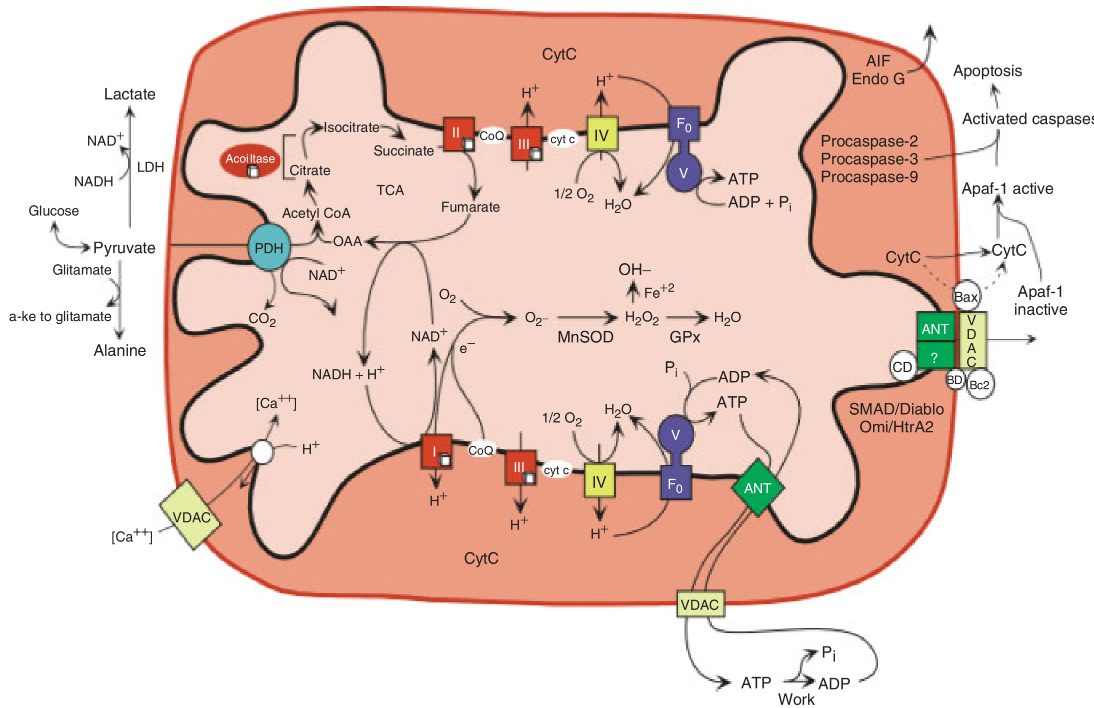

Figure 2 Three features of mitochondrial metabolism relevant to the pathophysiology of disease: (1) energy production by oxidative phosphorylation (OXPHOS), (2) reactive oxygen species (ROS) generation as a toxic by-product of OXPHOS, and (3) regulation of apoptosis through activation of the mitochondrial permeability transition pore (mtPTP). The energy that is released is used to maintain body temperature and to generate ATP. The reducing equivalents (electrons) from dietary calories are collected by the tricarboxylic acid (TCA) cycle and β-oxidation and transferred to either NAD^+ to generate NADH or FAD to give $FADH_2$. The electrons are then oxidized by the electron transport chain (ETC). NADH transfers electrons to complex I (NADH dehydrogenase) and succinate from the TCA cycle transfers electrons to complex II (succinate dehygrogenase) and both complexes transfer their electrons to ubiquinone (coenzyme Q_{10} or CoQ) to generate ubisemiquinone ($CoQH^{\cdot}$), and then ubiquinol ($CoQH_2$). From $CoQH_2$, the electrons are transferred to complex III, then cytochrome c, then complex IV, and finally to $\frac{1}{2}$ O_2 to give water. The energy that is released during electron transport is used to pump protons from the matrix out across the mitochondrial inner membrane to create an electrochemical gradient ($\Delta P = \Delta\Psi + \Delta\mu^{H+}$). This biological capacitor serves as a source of potential energy to drive complex V to condense ADP + Pi to give ATP. The mitochondrial ATP is then exchanged for cytosolic ADP by the ANT. The efficiency by which ΔP is converted to ATP is known as the coupling efficiency. Tightly coupled OXPHOS generates the maximum ATP and minimum heat, while loosely coupled OXPHOS generates less ATP but more heat. I, II, III, IV, and V = OXPHOS complexes I–V; ADP or ATP = adenosine di- or triphosphate; ANT = adenine nucleotide translocator, cytc = cytochrome c; GPx = glutathione peroxidase-1; LDH = lactate dehydrogenase; MnSOD = manganese superoxide dismutase or SOD2; NADH = reduce nicotinamide adenine dinucleotide; TCA = tricarboxylic acid cycle; VDAC = voltage-dependent anion channel

from of the misdirection of electrons from the early stages of the electron transport chain (ETC) surrounding $CoQH^{\cdot}$ directly to O_2 to generate superoxide anion ($O_2^{\cdot -}$). Superoxide anion is highly reactive, but can be detoxified by mitochondrial MnSOD to generate hydrogen peroxide (H_2O_2), which is relatively stable. However, in the presence of transition metals, H_2O_2 can be reduced to hydroxyl radical ($^{\cdot}OH$), which is the most toxic ROS. H_2O_2 can be detoxified by reduction to water by glutathione peroxidase (GPx1) or conversion to O_2 and H_2O by catalase (Figure 2). ROS damage mitochondrial proteins, lipids, and nucleic acids, which inhibit OXPHOS and further exacerbate ROS production. Ultimately, the mitochondria become sufficiently energetically impaired that they malfunction and must be removed from the tissue.

Cells with faulty mitochondria are removed by apoptosis (programmed cell death) through the activation of the mitochondrial permeability transition pore (mtPTP). The mtPTP is thought to be composed of the outer membrane voltage-dependent anion channel (VDAC) proteins, the inner membrane ANT, the pro- and antiapoptotic Bcl2-Bax gene family proteins, and cyclophillin D. This complex senses changes in the mitochondrial electrochemical gradient (ΔP), adenine nucleotides, ROS, and Ca^{++}, and when these factors get sufficiently out of balance, the mtPTP becomes activated and opens a channel between the cytosol and the mitochondrial matrix depolarizing ΔP and causing the mitochondrion to swell. Proteins from the mitochondrial intermembrane space are then released into the cytosol. Among these are cytochrome c that activates cytosolic Apaf-1 to convert procaspases 2, 3, and 9 to active caspases that degrade cellular and mitochondrial proteins. Apoptosis initiating factor (AIF) and Endonuclease G are transported to the nucleus where they degrade the nDNA (Figure 2).

3. Genetics of the nDNA mitochondrial genes and disease mutations

A variety of mitochondrial diseases result from mutations in the nDNA-encoded genes of the mitochondrial genome, and thus exhibit Mendelian inheritance. These can affect structural and assembly genes of OXPHOS, genes involved in mtDNA maintenance, and genes affecting mitochondrial fusion and mobility (Wallace and Lott, 2002; DiMauro, 2004) (Table 1).

4. Genetics of the mtDNA and degenerative diseases, cancer, and aging

In sharp contrast to the Mendelian inheritance of diseases resulting from nDNA mitochondrial mutations, diseases resulting from mutations in the mtDNA have a totally unique inheritance. In vertebrates, the mtDNA is inherited exclusively through the mother. However, each cell can harbor thousands of copies of the mtDNA, which can either be pure normal (homoplasmic wild type), a mixture of mutant and normal (heteroplasmic), or homoplasmic mutant. The percentage

Table 1 Diseases due to Mutations in nDNA Mitochondrial genes

Clinical disease	Mitochondrial defect	Genetic defect	References
Leigh syndrome	Complex I	Various structural genes	Procaccio and Wallace (2004), Smeitink and van den Heuvel (1999)
Leigh syndrome	Complex IV	SURF1 assembly	Tiranti *et al*. (1998), Zhu *et al*. (1998)

Peripheral neuropathy	Mitochondrial fusion and fission	Mitofusin 2 (MFN2)	Zuchner *et al*. (2004)

AD-CPEO: autosomal dominant – chronic progressive external ophthalmoplegia; MNGIE: mitochondrial neurogastrointestinal encephalomyopathy; AD-OPA: autosomal dominant optic atrophy.

of mutant mtDNAs determines the relative energy deficiency of the cell and thus the probability of apoptosis. The tissues most sensitive to the adverse effects of mitochondrial decline are the central nervous system, heart, muscle, renal, and endocrine systems, the tissues most affected in aging (Wallace and Lott, 2002).

Because of its chronic exposure to ROS, mammalian mtDNAs have a very high mutation rate. Hence, even though the human mtDNA is small, mtDNA diseases are common. Clinically relevant mtDNA mutations come in three classes: (1) recent maternal germline mutations frequently resulting in disease; (2) ancient polymorphisms, a subset of which permitted our ancestors to adapt to new environmental conditions; and (3) somatic mtDNAs that accumulate in postmitotic tissue mtDNAs with age (Wallace and Lott, 2002).

4.1. Recent pathogenic mutations

Recent pathogenic mutations include both base substitution and rearrangement mutations. Base substitution mutations can alter proteins or protein synthesis (rRNA and tRNA) genes. An example of a mtDNA missense mutation is the np 11778

mutation in ND4 (R340H), which causes Leber's Hereditary Optic Neuropathy (LHON), a form of sudden-onset, midlife blindness. An example of a protein synthesis mutation is the np 8344 in the $tRNA^{Lys}$ gene that causes Myoclonic Epilepsy and Ragged Red Fiber disease (MERRF). An extensive list of the known pathogenic mtDNA mutations is provided at our website "**www.mitomap.org**", and the characteristics of the diseases are given in two large reviews (Wallace and Lott, 2002; Wallace *et al*., 2001).

Rearrangement mutations can occur throughout the mtDNA, and can include both maternally inherited and spontaneous cases. Maternally inherited rearrangement mutations are most commonly associated with Type II diabetes and deafness, and are thought to be inherited as insertion mutations (Ballinger *et al*., 1992; Ballinger *et al*., 1994). Deletions in the mtDNA, with or without attendant insertions, are primarily spontaneous and result in multisystem disorders encompassing a continuum of phenotypes ranging from Chronic Progressive External Ophthalmoplegia (CPEO) to the more severe Kearns–Sayre syndrome. The most severe mtDNA rearrangement disorder is the Pearson's marrow pancreas syndrome, which frequently leads to death in childhood from pancytopenia. The range of mtDNA rearrangements is cataloged at **www.mitomap.org**.

mtDNA diseases can affect the central nervous system, diminishing vision, hearing, movement, balance, and memory; muscle causing progressive weakness; heart leading to hypertrophic and dilated cardiomyopathy; the endocrine system resulting in diabetes mellitus, and the renal system. Hence, it is now clear that mitochondrial defects represent one of the most common forms of human inborn errors of metabolism (Wallace and Lott, 2002).

The pathogenicity of mildly deleterious mtDNA mutations can also be augmented when the mutation occurs on regional mtDNAs that harbor ancient adaptive mtDNA polymorphisms. For instance, LHON can be caused by a number of mtDNA point mutations in the *ND* genes. The more biochemically severe mutations cause LHON independent of the background mtDNA, but the milder ND mutations such as np 11778, 14484, and 10663 cause LHON when they co-occur with the European mtDNA lineage J.

4.2. *Ancient adaptive mtDNA mutations*

The mtDNAs of indigenous human populations around the world harbor region-specific mtDNAs that encompass groups of related haplotypes, called *haplogroups*. These haplogroups arose a people migrated out of African into Eurasia and ultimately into the Americas.

The mtDNA history is remarkable for the striking discontinuities that exist between the extensive mtDNA variation of Africa from which only two mtDNA lineages (M and N) occupied all of Eurasia and the plethora of Asian mtDNA types of which only three haplogroups (A, C, and D), and much later G came to occupy the extreme northeastern Chukotka Peninsula of Siberia. These discontinuities strikingly correlate with latitude and thus the climate. This led to the hypothesis that certain mtDNA haplogroups acquired functional mutations that decreased the coupling efficiency, increasing mitochondrial heat production that permitted people to adapt to the increasing cold of the more northern latitudes.

This hypothesis is supported by the fact that missense mutations in mtDNA protein genes show regional specificity. Missense mutations are prevalent in the *ATP6* gene in the arctic, in the *cytb* gene in Europe, and in the *COI* gene in Africa. Mutations in different *ND* genes also show regional correlation (Mishmar *et al*., 2003). Moreover, many of the ancient missense mutations change amino acids that are as highly evolutionarily conserved as are most known pathogenic mutations, yet have been retained in the human population for tens of thousands of years. Hence, they could not be pathogenic in the environment in which they reside, but rather must be adaptive and thus beneficial. Furthermore, an analysis of the cytb missense mutations for which there is a complex III crystal structure revealed that many of these missense mutations affected CoQ binding sites, which would alter the Q-cycle and thus proton pumping (Ruiz-Pesini *et al*., 2004).

Finally, when the European mtDNA haplogroups were correlated with longevity and predisposition to Alzheimer disease (AD) and Parkinson disease (PD), it was found that mtDNAs harboring uncoupling variants were enriched in the elderly and deficient in AD and PD patients. This led to the conclusion that the uncoupling mutations must enhance the flow of electrons through the ETC, keeping the ETC carriers oxidized. This, in turn, reduces the spurious transfer of electrons to O_2 to generate ROS and associated mitochondrial and cellular damage.

These same uncoupling mutations would also reduce the efficiency of ATP generation that would then exacerbate the ATP deficiencies resulting from the milder mtDNA mutations. This could account for the predilection of LHON patients harboring the milder mtDNA mutations to also have haplogroup J mtDNAs, which harbor either the np 14798 or np 15257 cytb missense mutations. Thus, ancient adaptive mtDNA variants are affecting individual predisposition to degenerative diseases and aging today.

4.3. Somatic mtDNA mutations

Postmitotic tissues also accumulate somatic mtDNA mutations with age. These can be rearrangement, coding region base substitution, and CR mutations. Since mtDNA diseases generally have a delayed-onset and progressive course and affect the same tissues and generate the same symptoms as aging, it has been hypothesized that the accumulation of somatic mtDNA mutations results in the age-related decline in mitochondrial function that ultimately results in degenerative diseases and the senescence of aging (Wallace and Lott, 2002).

Consistent with these concepts, mtDNA deletions have been found to accumulate with age in those tissues most prone to age-related decline. Also, mtDNA CR mutations have been found to accumulate in various tissues including fibroblasts, muscle, and brain (Michikawa *et al*., 1999; Coskun *et al*., 2003)

Somatic mtDNA mutations have also been found in a variety of solid tumors including prostate, breast, colon, bladder, head, and neck tumors. In prostate cancer, a study of the *COI* gene revealed that both germline and somatic mtDNA mutations were associated with prostate cancer. Moreover, the substitution of a mtDNA harboring a known pathogenic mutation for the resident mtDNAs of a prostate cancer cell line increased tumor growth, while substitution of the same mtDNA but with the

normal base inhibited tumor growth. This increased tumorigenicity was associated with increased ROS production. Therefore, mtDNA mutations that increase ROS production may also be important factors in tumorigenicity (Petros *et al*., 2005).

Somatic mtDNA mutations may also be a major contributor to age-related neurodegenerative diseases including AD. A survey of the mtDNA CRs of AD brains revealed that 65% harbored the T414G mutations in the mtTFA binding site for P_L, while none of the controls harbored this mutation. Moreover, the AD brains had an overall 73% increase in CR mutations. Finally, these mutations were preferentially located in CR regulatory elements and were associated with a 50% reduction in mtDNA copy number and a 50% reduction in the L-strand ND6 transcript (Coskun *et al*., 2004). Hence, mtDNA CR mutations may be an important factor in the development of neurodegenerative disease.

5. Conclusion

The distribution of the genes of the mitochondrial genome between the high copy-number, maternally inherited mtDNA and the low copy-number, Mendelian nDNA results in a complex genetics with both quantitative and quantized genetic elements. As a result, the mitochondrial genome provides the necessary features to explain the complex inheritance, delayed onset, and progressive course of the age-related degenerative diseases, aging, and cancer. Only the mtDNA is present in sufficient copies within each cell to permit a progressive accumulation of somatic mtDNA mutations, thus providing an aging clock. Moreover, the central role of the mitochondria in energy production, ROS generation, and apoptosis regulation links dietary intake with genetic predisoposition, a common hallmark of degenerative diseases and cancer. Hence, if we are to understand the common degenerative diseases, aging, and cancer, we must understand the genetics and pathophysiology of the mitochondrion.

Introductory Review

Approach to rare monogenic and chromosomal disorders

Marc S. Williams
Gundersen Lutheran Medial Center, La Crosse, WI, USA

1. Introduction

Medical geneticists are asked to evaluate a wide variety of conditions. These include congenital malformations (single and multiple), mental retardation, neurologic disorders, inborn errors of metabolism, chromosomal abnormalities, hereditary cancer syndromes, disorders of hearing and vision, teratogenic exposures, and families with multiple affected members. It is the medical geneticist's job to ascertain and analyze information from a variety of sources in order to establish a diagnosis coordinate testing initiate treatment explain inheritance, recurrence risk, and prognosis; and ultimately assist in the coordination of care for the individual and family.

The purpose of this chapter is to introduce the reader to the genetic evaluation of rare monogenic and chromosomal disorders. The author invites the reader to "observe" a hypothetical clinic visit, with explication, to illustrate this concept.

2. Patient evaluation

2.1. Chief complaint

The patient is a 45-year-old female referred by her internist to a multidisciplinary clinic for evaluation of mental retardation and unusual behaviors.

The central element of any medical encounter is the history and physical. Information gathered from this process allows generation of a differential diagnosis that becomes the basis for subsequent investigation to establish a definite diagnosis. Experienced practitioners recognize that this is a dynamic process that begins with the chief complaint and is constantly modified throughout the encounter. As information is acquired, subsequent questions are added, subtracted, or modified to refine the differential. While this process is hardly unique to the genetics clinic, the range of information required is generally much broader. Typically, this will involve review of primary medical records as well as obtaining history from the patient, or, in the case of this patient, from a parent or reliable caretaker. While

the differential is of necessity broad at this point, we know that the diagnosis must be restricted to congenital disorders and involve mental retardation. This could include chromosome disorders (although Trisomies 13 and 18 can likely be ruled out due to the patient's age, and so is Down Syndrome, given that this is a highly recognizable disorder), inborn errors of metabolism (including Phenylketonuria (PKU) and congenital hypothyroidism, as the patient was born before routine newborn screening), multiple congenital anomaly syndromes, congenital infection, perinatal accident, and teratogenic exposures.

2.2. Patient history

Preclinic records review. Pregnancy was complicated by possible exposure to "Asian flu". Delivery was described as "delayed", without additional explanation. She was described as a poor feeder with a poor suck, but no other neonatal information was available. She was institutionalized in a center for handicapped children at age 3, where she remained until discharge to a group home at age 33. She was noted to fall easily and had several fractures relating to falls. Of note was a neck injury secondary to a fall that resulted in a central cord syndrome, which was thought to explain her predisposition to falls. Diagnoses included profound mental retardation, impulse control disorder with self-injurious behavior, episodic depression, and possible seizure disorder. Previous evaluation included a head CT scan, which was normal; MRI of the cervical spine showing degenerative changes of C3-C6 vertebral bodies, but no changes in the cord; normal Thyroid stimulating hormone (TSH) on several occasions; an EEG (just prior to this evaluation) that showed multifocal epileptiform discharges without a clear clinical correlate; normal hearing; myopia; and exotropia. IQ testing done 10 years previously gave a mental age estimate between 9 and 14 months. Review of the previous intellectual assessments ruled out deterioration of function over time. She never developed speech. She was on multiple medications, including several psychotropic medications to attempt to control behavior and two anticonvulsants. The anticonvulsants were being tapered, given the lack of clinically evident seizures.

On the basis of record review, congenital hypothyroidism can be ruled out. There was history of an illness during the pregnancy. If the "Asian flu" was, in fact, one of the TORCH infections (Toxoplasmosis, Other, Rubella, Cytomegalovirus, Herpes) this could explain the patient's problems. Other acquired causes of retardation such as CNS infection can be ruled out. Disorders with short stature (height reported was 165 cm) or structural CNS anomalies can also be eliminated. The degree of mental retardation is profound, but the effects of institutionalization on ultimate intellectual function, while subject to debate, could have had an effect (Russell et al., 1986; Silverstein, 1962, 1969; Sternlicht and Siegel, 1968). Progressive neurologic disorders can be eliminated from the differential, as the patient has a chronic static encephalopathy. The question of seizures is important given the history of frequent falls and the abnormal EEG findings, even in the absence of clinically apparent seizures. Additional information will be needed to characterize the behavioral issues. Attempts to obtain family history will be critical to knowing whether this

is an isolated case in the family. A specific diagnosis, Angelman syndrome, had moved to the top of the author's differential diagnosis at this point.

2.3. Office visit

The patient was accompanied to the office visit by her group home worker. Her parents were her legal guardians, but lived in another state. The worker was unable to provide any additional information about past medical or family history. She did indicate that the patient was generally happy and that there were no specific behavioral issues currently. She confirmed that the patient had an unsteady gait, but did not walk with arms extended (something that can be seen in Angelman syndrome). No obvious seizure manifestations, including staring spells, unresponsiveness, or incontinence, were noted. The patient is generally healthy with the exception of injuries from falls. A complete review of systems did not reveal any other concerns. (NB: The genetic review of systems includes the usual medical information, but adds information specific to genetic disorders such as unusual odors, intolerance to certain foods or fasting, response to illness and cyclical patterns of illness. Presence of some or all of these findings strongly suggests an inborn error of metabolism, with buildup of toxic compounds leading to symptoms.)

Given the lack of early information, the parents were contacted by phone. The mother indicated that her pregnancy was normal, and she did not have any complications, exposures, or illnesses. She indicated that her physician explained that the retardation was due to a problem with the pregnancy or delivery, despite the lack of any pregnancy complications, a normal vaginal delivery at term, and no neonatal difficulties other than the feeding difficulties. (It should be noted that in virtually all patients born before 1970, and in many born after, the cause is given as problems with pregnancy or delivery, or high fever. Rarely is there evidence to implicate either. This reflects a lack of information about the etiology of birth defects and mental retardation at that time that persists to some degree even to the present day). The parents were encouraged by their physician to institutionalize the patient.

2.4. Family history

No information was available in the medical record. The parents indicated that the family history was unremarkable for any other individual affected with mental retardation, seizures, congenital malformations, or multiple miscarriages. The patient's siblings were all healthy, but several expressed concerns about having a child similar to the patient.

In this case, the family history is not helpful in the differential diagnosis. In many cases, however, the family history provides the information crucial to diagnosis. The genetic family history (or pedigree) is a structured ascertainment of disease in at least three generations of both the maternal and paternal families, which, in addition, may require confirmation of diagnosis, age at diagnosis, pathologic

diagnosis, and ethnicity, as well as other information not collected in a traditional family history (Aase, 1990; Scheuner et al., 1997; see also Article 78, ***Genetic family history, pedigree analysis, and risk assessment****, Volume 2). This information is frequently subjected to formal probability analysis in order to appropriately quantify risk for the consultand (Gelehrter and Collins, 1990; see also Article 78,* ***Genetic family history, pedigree analysis, and risk assessment****, Volume 2). In many monogenic disorders, the family history is the best "genetic test" that can be done.*

2.4.1. Caveat #1: beware the mythology of the medical record

The reader will note several inconsistencies in the history of the case under discussion. Most notable is the history from the mother that she did not experience illness during the pregnancy. While this does not completely eliminate intrauterine infection from the differential diagnosis, it makes it less likely. Having reviewed thousands of medical records, it is eye-opening to see how frequently information is inaccurate. In many cases, an error can be identified that is propagated by the practice of copying what is in the last note. Because of this practice, many records resemble the garbled message that results from the old party game, "Telephone". Confirmation of information from primary sources, when available, is absolutely critical to arriving at an accurate diagnosis, not to mention preventing inappropriate treatment decisions based on the inaccurate information.

2.5. Physical examination

The patient appeared well. Current weight was 55 kg (30th percentile) and height was 165 cm (75th percentile). Head circumference was 53.3 cm (3rd percentile). She had upslanting palpebral fissures but no epicanthic folds. The nose was long with a pointed tip. The mandible was prominent. Cardiothoracic and abdominal exams were unremarkable. She had a moderate scoliosis of the spine. Extremities were unremarkable, except for scarring from biting. Neurologic examination was remarkable for increased muscle tone, and hyperreflexia. Strength was normal. Her gait was wide-based and unsteady, although she did not use her arms for balance. Measurements of facial features (eye spacing, ear length, philtrum length), hands, digits, and feet were within normal limits.

The genetic examination includes not only a full physical and neurologic examination but also examination for the so-called minor anomalies (see Article 79, ***The physical examination in clinical genetics****, Volume 2). Minor anomalies are defined as unusual morphologic features (usually defined as present in less than 3% of the referent population) of no serious medical or cosmetic significance (Jones, 1997; Merks et al., 2003). Patients must be compared to the relevant ethnic group (e.g., upslanting palpebral fissures and epicanthic folds are minor anomalies in Caucasians but not in Asians). Also, some minor anomalies (e.g., preauricular pits or polydactyly) can be inherited in families in an autosomal dominant fashion. Other minor anomalies, such as eye spacing, short fingers, and so on, require measurement for confirmation. Standards for comparison are available (Saul et al., 1998; Hall et al., 1989). For further information on the dysmorphologic history and physical*

examination, the reader is referred to Diagnostic Dysmorphology (Aase, 1990; see also Article 79, ***The physical examination in clinical genetics****, Volume 2). This patient has the following minor anomalies: microcephaly, upslanting palpebral fissures, unusual nose, and prominent mandible.*

Another important aspect of the genetic examination is the concept of the gestalt. The best example of this is Down syndrome, a condition familiar to physicians and lay people alike. While one can make a list of the multiple minor anomalies present in a given individual with Down syndrome, one look at the face allows the diagnosis to be made in virtually all patients, regardless of age or ethnicity. This recognition of the pattern represents the gestalt, or whole is greater than the sum of the parts. Many other genetic conditions are equally distinctive and recognizable (in fact, the most used text of dysmorphologists is titled Recognizable Patterns of Human Malformation (Jones, 1997)). However, because they are much less frequent, most nongeneticists do not recognize the specific disorders. This patient's gestalt is consistent with Angelman syndrome, the top differential diagnosis at this point.

2.6. Synthesis

Table 1 shows the relevant points of this patient's history and physical examination. Genetic diagnosis lends itself to hierarchical search strategies using a variety of public and proprietary tools (Bankier and Danks, 2000; NCBI PubMed, 2004; OMIM, 2000; Winter and Baraitser, 2002; *see also* Article 86, **Uses of databases**, Volume 2). Before demonstrating this approach, it is important to discuss the use of "handles". A handle is a slang term for a relevant item of history or physical examination. In this patient, any of the items listed in Table 1 could be used as a handle. Handles can be used singly, but are more frequently used in combination to develop and prioritize the differential diagnosis.

2.6.1. Caveat #2: choose your handles wisely

Handles vary in their utility for this purpose. Using OMIM (Online Mendelian Inheritance in Man) as an example, consider the following searches. As might

Table 1 Relevant clinical information

History	Physical
Normal pregnancy	Microcephaly
Congenital	Upslant palpebral fissures
Mental retardation–profound	Long, pointed nose
Abnormal EEG	Prominent mandible
Possible clinical seizures	Hypertonicity
No speech	Ataxia
Absence of major birth defects	
Normal neuroimaging	
Susceptible to falls	
Episodic depression	
Negative family history	

be expected, a search on "mental retardation" would yield thousands of possible diagnoses (1157 entries). Using modifiers such as profound can limit the diagnoses some (97 entries) but not to the point of generating a useable list. Searching on the term ataxia would yield a slightly smaller list of diagnoses (552 entries). Ataxia is a bit more specific than mental retardation. Similarly, through experience, geneticists recognize that upslanting palpebral fissure is not a good handle, while prominent mandible is less common, therefore more specific. The true power lies in combining more specific search terms. By searching on mental retardation and ataxia, 165 entries are identified. If one adds seizures to these two, the list is further pared to 72 entries, with Angelman syndrome appearing second on the list. Adding the physical feature "prominent mandible" to the search produces one entry in OMIM – the gene for Angelman syndrome. The problem with being too specific is that other potential diagnoses can be missed. For example, if PubMed (NCBI PubMed, 2004) is searched on that specific combination, there are no "hits". It is always appropriate to try different combinations of search terms and identify common diagnoses that appear. Table 2 shows the results of the search "mental retardation + seizures + ataxia" in several different tools. Individual diagnoses are grouped

Table 2 Top search results for mental retardation + seizures + ataxia

PubMed-limit Human (93 citations)[a]	OMIM (72 hits first 10 listed)[b]	POSSUM (84 hits)[c]
Rett syndrome (14)	Ataxia-telangiectasia	Chromosomal (11)
Angelman syndrome (12)	Partington X-linked MR syndrome	Metabolic (18)
Mitochondrial (6)	Rett syndrome	Teratogen (2)
Dentatorubral-pallidoluysian atrophy (4)	Disorders of pyruvate metabolism	Angelman syndrome
Other known single gene disorders (16)	Leukoencephalopathy vanishing white matter	Rett syndrome
Metabolic disorders (15)	Angelman syndrome	Single gene disorders/unique cases (51)
Unique case reports/new syndromes (7)	Polymicrogyria frontoparietal	
Chromosome disorders excluding Angelman (1)	ATP synthase 6	
Acquired disorders (7)	Neimann–Pick Type C	
Not relevant (9)	Dentatorubral-pallidoluysian atrophy	

[a]PubMed search produces a citation list. Individual disorders with more than four citations are listed separately, while the rest are grouped into larger categories.
[b]Online Mendelian Inheritance in Man (OMIM) searches are ranked according to "relevance". The database decisions that determine relevance are not explicated. This leads to differences in hierarchy when compared to the other two tools. Chromosome abnormalities are not listed in OMIM for the most part.
[c]POSSUM Mental retardation was specified as moderate-severe. Dentatorubral-pallidoluysian atrophy did not appear. This syndrome is not included in this database. If microcephaly and prognathism are added, only five disorders have all five traits, Angelman syndrome, Carbohydrate deficient glycoprotein syndrome, deletion 18q, microcephaly with chorioretinopathy, and X-linked mental retardation-Christianson type.

Table 3 Differential diagnosis

Rett syndrome
Angelman syndrome
Dentatorubral-pallidoluysian atrophy
Other chromosomal anomalies
Metabolic disorder
Monogenic disorder

into major diagnostic categories. These are combined into the differential diagnosis in Table 3.

2.7. Confirmation

The purpose of the preceding exercise is to generate and rank order a differential diagnosis. This allows for a rational approach to diagnostic testing. There are so many available tests, with more coming on line each day that a nondirected approach will result in great expenditure of resources with minimal likelihood of success. Put another way, there is no genetic "chem-20". Let us examine the differential diagnosis from Table 3.

Chromosome deletion or duplication: This is a very common consideration in patients such as this one. High-resolution chromosome analysis is a general screen for these disorders. If the deletion or duplication is large enough, a cytogeneticist will be able to identify the affected chromosomal segment, which will allow comparison to other cases reported in the literature. It is now known that many of these abnormalities are smaller than the resolution of standard microscopy (*see* Article 17, **Microdeletions**, Volume 1). Molecular genetics is providing tools such as fluorescence-in-situ-hybridization (FISH) (*see* Article 22, **FISH**, Volume 1) and comparative genomic hybridization (CGH) (*see* Article 23, **Comparative genomic hybridization**, Volume 1) to identify smaller abnormalities. Some of these techniques require a suspected diagnosis (e.g., Velo-Cardio-Facial syndrome can be diagnosed by using a specific FISH probe for chromosome 22q11 that will detect the relevant deletion (*see* Article 87, **The microdeletion syndromes**, Volume 2)), while others may be used for whole-genome screening (although the resolution of these techniques currently is not sufficient to supplant standard chromosome analysis).

2.8. Monogenic disorder

The tests to confirm these disorders, for the most part, depend on making a tentative diagnosis. Exceptions would include biochemical analysis of amino acids (*see* Article 70, **Advances in newborn screening for biochemical genetic disorders**, Volume 2) and organic acids (*see* Article 70, **Advances in newborn screening for biochemical genetic disorders**, Volume 2) that can screen for a variety of disorders. The tests can include simple biochemical assays (serum lactate and pyruvate for disorders of pyruvate metabolism (*see* Article 70, **Advances in newborn screening for biochemical genetic disorders**, Volume 2)), protein electrophoresis (transferrin

electrophoresis for Carbohydrate Deficient Glycoprotein syndrome (*see* Article 70, **Advances in newborn screening for biochemical genetic disorders**, Volume 2)), cell-based functional assays (mitochondrial and respiratory chain disorders (*see* Article 70, **Advances in newborn screening for biochemical genetic disorders**, Volume 2)), and direct mutation analysis (MECP2 sequencing for Rett syndrome (*see* Article 89, **Familial adenomatous polyposis**, Volume 2) or measurement of the size of the trinucleotide repeat for dentatorubro-pallidoluysian atrophy (*see* Article 89, **Familial adenomatous polyposis**, Volume 2)).

2.9. Angelman syndrome

The pathogenesis of this disorder demonstrates causal heterogeneity. It can be caused by deletions, both macroscopic and microscopic, in the maternal chromosome 15q11-13, paternal uniparental disomy 15 (*see* Article 29, **Imprinting in Prader–Willi and Angelman syndromes**, Volume 1), abnormal imprinting of chromosome 15 (*see* Article 29, **Imprinting in Prader–Willi and Angelman syndromes**, Volume 1), and mutations in the *UBE3A* gene (*see* Article 89, **Familial adenomatous polyposis**, Volume 2). Thus, Angelman syndrome can be a chromosomal disorder (most common) or a monogenic disorder. To further complicate matters, similar clinical features have been seen in females with mutations in the *MECP2* gene on the X chromosome that is usually associated with Rett syndrome (*see* Article 89, **Familial adenomatous polyposis**, Volume 2). This phenocopy has features of both Angelman and Rett syndrome. On the basis of the differential diagnosis, the best first test would be high-resolution chromosome analysis, followed by specific testing for Angelman syndrome if the chromosomes were negative. In this patient, chromosome analysis revealed a visible deletion of 15q11-13, confirming the diagnosis of Angelman syndrome. (For the reader interested in more information on testing for Angelman syndrome, please see Diagnostic Testing for Prader-Willi and Angelman Syndromes: Report of the ASHG/ACMG Test and Technology Transfer Committee **http://www.acmg.net/resources/policies/pol-024.asp**).

2.10. Rationale

The core tenet of clinical genetics is that establishing a specific and accurate diagnosis confers significant benefit to the patient and family. These may include elimination of unnecessary tests, information about recurrence risks for reproductive decision making, initiation of therapies to improve health, condition-specific anticipatory guidance (Cassidy and Allanson, 2001), and insight into prognosis for the disorder. In this case, the diagnosis led to several tangible benefits. The anticonvulsant taper was stopped, as seizures are a universal feature of Angelman syndrome. Additionally, a medication being used for management of behavior that lowers the seizure threshold was changed to one that does not have that effect. The patient's siblings were informed that they were not at increased risk for having an affected child with Angelman syndrome. Finally, and perhaps most importantly, at the informing session with the parents, both parents wept with joy that a diagnosis

had been made. The mother expressed how the guilt she experienced because of the diagnosis of birth injury had never left her. A simple explanation that this occurred by accident and was outside of anyone's control provided release of this guilt that 45 years had not diminished.

2.10.1. Caveat #3 (aka Bryan Hall's rule #1): no diagnosis is better than the wrong diagnosis

In this case, the "diagnosis" of birth injury stifled clinical investigation of the etiology of this patient's problems for over 40 years. She and her family were unable to benefit from the information a specific diagnosis would have provided for this entire time. It should be noted, however, that Angelman syndrome was not described until this patient was 10 years old (Angelman, 1965).

2.10.2. Caveat #4: there is no statute of limitations on diagnostic investigations

It is important to recognize that in many cases serial evaluation of patients is necessary to establish a diagnosis. Frequently, the changing phenotype with age provides the necessary clues to a diagnosis. As important is the rapid increase of knowledge about the genetic cause of disorders and description of new disorders that will, as in this case, allow for a diagnosis to be made in time.

In conclusion, the evaluation of chromosomal and monogenic disorders requires a systematic approach to gather information, identify handles, develop a differential diagnosis, prioritize diagnostic investigations, and, hopefully, arrive at a specific diagnosis.

Introductory Review

Approach to common chronic disorders of adulthood

Maren T. Scheuner
UCLA School of Public Health, Los Angeles, CA, USA

1. Introduction

Common disease genetics is the study of genetic aspects of diseases that are major public health concerns, such as coronary heart disease, stroke, cancer, and diabetes (American Heart Association, 2002; American Cancer Society, 2003). These are diseases of affluence that have increased in prevalence since industrialization of our society because of inactivity, excess calories, processed foods, tobacco use, radiation, and pollution. These diseases are chronic conditions that develop over decades, usually occurring in adulthood. Early disease detection and prevention are possible because of the chronic nature of these disorders.

Common chronic diseases are considered complex genetic conditions because of genetic and nongenetic/environmental risk factors. For any given disorder, in some individuals, the interaction of multiple genetic factors may explain most of the disease susceptibility (i.e., polygenic inheritance), whereas in others, environmental factors predominate. However, in most cases, disease is due to the interaction of genetic and environmental risk factors (i.e., multifactorial inheritance). This is in contrast to the classical paradigm of genetic disease, where a single gene mutation is usually sufficient for disease expression. Rarely, common chronic diseases of adulthood can occur primarily as the manifestation of a single gene mutation. However, even in these cases, there is substantial clinical heterogeneity (Scheuner *et al*., 2004).

The ability to identify genetic susceptibilities to common chronic diseases has the potential to improve our efforts in diagnosing, treating, and preventing these conditions. Because the environmental risk factors for common chronic diseases have become so pervasive in our society, our genetic susceptibilities are readily revealed. This is especially true for most individuals diagnosed with a common chronic disease at an early age (about 10 to 20 years earlier than the typical age of diagnosis). In addition, because a variety of chronic diseases can be linked to each environmental risk factor (e.g., coronary artery disease, lung cancer, and emphysema are all associated with smoking), genetic susceptibilities become paramount in determining which individuals have the greatest risk for developing a specific disease, given a particular exposure or lifestyle.

2. Genetic risk assessment strategies

Genetic susceptibility to common disease can be assessed by several approaches, including DNA-based testing, phenotypic assessment of biochemical and physiological traits, as well as personal and family history collection and interpretation. Each approach may be used in the clinical setting when performing individualized risk assessment. However, in population-based settings, the approach used to identify individuals with a genetic risk is influenced by the prevalence of genetically determined disease and the accuracy, reliability, and acceptability of the screening method.

Currently, family history collection and interpretation is the most practical population-based strategy for identifying individuals with a genetic susceptibility to many common chronic diseases (Scheuner *et al*., 1997a). It represents complex interactions of genetic, environmental, cultural, and behavioral factors shared by family members. For many common diseases, a positive family history is quantitatively significant with relative risks ranging from 2 to 5 times those of the general population, and this risk generally increases with an increasing number of affected relatives and earlier ages of disease onset (Table 1). Family history characteristics that increase disease risk include early age at diagnosis, two or more close relatives affected with a disease or a related condition, a single family member with two or more related diagnoses, multifocal or bilateral disease, and occurrence of disease in the less-often affected sex. By recognizing the magnitude of risk associated with these familial characteristics, stratification into different familial risk groups (e.g., low, intermediate, and high) is possible (Table 2), which can guide risk-specific recommendations for disease management and prevention (Figure 1). Referral for genetic evaluation by a geneticist or other specialist should be considered for individuals with high familial risk.

Family history is a prevalent and relatively accurate predictor of risk for several chronic conditions, including many forms of cancer, coronary heart disease, stroke,

Table 1 Risk estimates due to family history for selected common chronic diseases of adulthood

Disease	Risk due to family history
Coronary heart disease	OR = 2.0 (one first-degree relative) (Ciruzzi *et al*., 1997)
	OR = 5.4 (two or more first-degree relatives) (Silberberg *et al*., 1998)
Type 2 diabetes	RR = 2.4 (mother) (Klein *et al*., 1996)
	RR = 4.0 (maternal and paternal relatives) (Bjornholt *et al*., 2000)
Osteoporosis	OR = 2.0 (female first-degree relative) (Keen *et al*., 1999)
	RR = 2.4 (father) (Fox *et al*., 1998)
Asthma	OR = 3.0 (mother) (Tariq *et al*., 1998)
	RR = 7.0 (father and mother) (*American Journal of Respiratory and Critical Care Medicine*, 1997)
Breast cancer	RR = 2.1 (one first-degree relative) (Pharoah *et al*., 1997)
	RR = 3.9 (three or more first-degree relatives) (Collaborative Group, 2001)
Colorectal cancer	OR = 1.7 (one first-degree relative) (Fuchs *et al*., 1994)
	OR = 4.9 (two first-degree relatives) (Sandhu *et al*., 2001)
Prostate cancer	RR = 3.2 (one first-degree relative) (Cerhan *et al*., 1999)
	RR = 11.0 (three first-degree relatives) (Steinberg *et al*., 1990)

Table 2 Suggested guidelines for risk stratification based on family medical history of common chronic diseases of adulthood

Low familial risk

1. No affected relatives.
2. Family medical history unknown.
3. Adopted person with unknown family medical history.
4. Only one affected second-degree relative with any age of disease onset from one or both sides of the pedigree if the disease is not sex-limited.
5. If the disease is sex-limited, only one affected second-degree relative with any age of disease onset from the parental lineage of the more-often affected sex.
6. If the disease is sex-limited, only one affected second-degree relative with a late or unknown age of disease onset from the parental lineage of the less-often affected sex.

Intermediate familial risk

1. Only personal history with a later age of disease onset.
2. Only one affected first-degree relative with late or unknown age of disease onset.
3. Only two affected second-degree relatives from one lineage with a late or unknown age of disease onset.
4. If the disease is sex-limited, only one affected second-degree relative with an early age of disease onset from the parental lineage of the less-often affected sex.

High familial risk

1. Personal history with an early age of disease onset.
2. Personal history with a late or unknown age of onset and personal history of a related condition at any age of onset.
3. Personal history with a late or unknown age of disease onset and one affected first- or second-degree relative with an early age of disease onset, or one affected first- or second-degree relative with a late or unknown age of disease onset and a related condition in the same relative.
4. One affected first-degree relative with an early age of disease onset.
5. If the disease is sex-limited, one affected second-degree relative with an early age of disease onset in the less-often affected sex.
6. Two affected first-degree relatives with a late or unknown age of disease onset.
7. One affected first-degree relative with a late or unknown age of disease onset and one affected second-degree relative with an early age of disease onset, or one affected second-degree relative with a late or unknown age of disease onset and a related condition in the same relative.
8. Two affected second-degree relatives from the same lineage with at least one having an early age of disease onset, or both having a late or unknown age of disease onset and at least one having a related condition.
9. Three or more affected first- and/or second-degree relatives from one lineage with any age of disease onset.
10. One first- or second-degree relative with an early age of disease onset and two first- and/or second-degree relatives from the same lineage with related conditions.
11. "Intermediate familial risk" on both sides of the pedigree.

Adapted from Scheuner *et al*. (1997a). Early age of disease onset refers to disease that occurs about 10 to 20 years earlier than typical. Examples of sex-limited diseases include coronary heart disease, osteoporosis, breast cancer, ovarian cancer, and prostate cancer. Examples of related conditions include coronary heart disease, diabetes and stroke, or colorectal cancer, endometrial cancer, and ovarian cancer.

and diabetes. About 43% of healthy, young adults will have a family history for one of these disorders. Depending upon the specific disorder, approximately 5–15% will have a moderate familial risk (about 2 times the population risk) and 1–10% a high familial risk (about 3–5 times the population risk, approaching risks associated with Mendelian disorders) (Scheuner *et al*., 1997b). Most sensitivity values for a positive

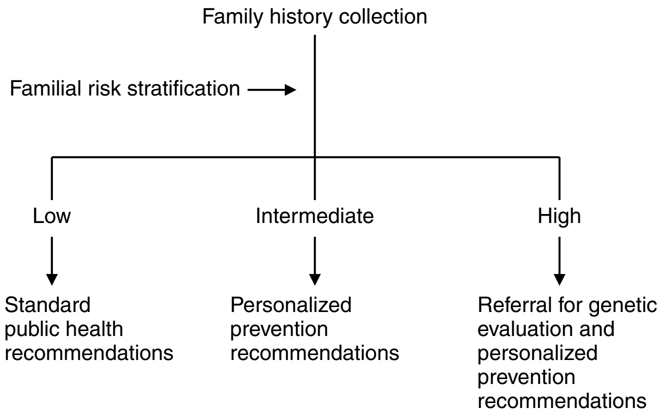

Figure 1 Family history collection followed by risk stratification that recognizes family history characteristics that increase disease risk (e.g., early age at diagnosis, two or more close relatives affected with a disease or a related condition, a single family member with two or more related diagnoses, multifocal or bilateral disease, and occurrence of disease in the less often affected sex) can guide risk-specific recommendations for disease management and prevention. Standard public health messages would be appropriate for individuals with a low familial risk. Personalized prevention recommendations should be provided to individuals with intermediate and high familial risk such as lifestyle changes if indicated, earlier and more frequent screening if appropriate, and use of chemoprevention when available. Referral for genetic evaluation by a geneticist or other specialist should be considered for individuals with high familial risk

family history of these diseases in a first-degree relative range from 70 to 85% and specificity is usually 90% or greater (Love *et al*., 1985; Hunt *et al*., 1986; Acton *et al*., 1989; Kee *et al*., 1993; Bensen *et al*., 1999). Overall, the available studies suggest that a positive family history can generally be used with a high degree of confidence for the identification of individuals at increased risk for developing many common chronic diseases.

Although numerous susceptibility alleles for common chronic diseases have been discovered, there has been limited progress in the discovery of genes for non-Mendelian forms of these diseases that have meaningful clinical relevance (Glazier *et al*., 2002). Thus, DNA-based testing for common chronic diseases is not a practical population-based approach for genetic risk assessment. Before testing for low-risk susceptibility genes has widespread clinical application, additional studies are needed to assess the prevalence and penetrance of these genotypes, as well as the effect of other genes and environmental factors on their expression. Furthermore, the clinical utility of DNA-based testing for disease susceptibility compared to other risk assessment strategies, including familial risk assessment and assessment of biochemical risk factors, must be proven.

Currently, genetic testing for chronic disease susceptibility is generally only available for rare Mendelian disorders. Personal and family history characteristics are crucial for identifying Mendelian disorders (Scheuner *et al*., 2004); therefore, genetic testing will likely remain a clinical intervention based on familial characteristics for many years to come. Thus, use of family history is central to providing access to genetic testing services that are currently available, and it is likely the

paradigm of familial risk assessment will inform future genetic testing of less penetrant susceptibility alleles.

3. Genetic evaluation for common chronic diseases

Clinical genetic evaluation for common disease should be performed for individuals with a high familial risk or when a Mendelian disorder is suspected. Genetic evaluation is composed of several components. The process includes (1) genetic counseling and education, (2) risk assessment and diagnosis using personal and family medical history, physical examination, and genetic testing, and (3) recommendations for management and prevention options appropriate for a genetic risk.

3.1. Genetic counseling and education

An important goal of genetic evaluation for common chronic diseases is the development of individualized preventive strategies based on the genetic risk assessment, the patient's personal medical history, lifestyle, and preferences. Genetic counseling is critical for delineating a patient's motivation and likely responses to learning of a genetic risk. Through genetic counseling, patients will be educated about the role of behavioral and genetic risk factors for disease, the mode of inheritance of genetic risk factors, and the options for prevention and risk factor modification.

This is a necessary process for individuals at risk for common chronic diseases since there is evidence that awareness of increased risk because of genetic or familial factors does not automatically translate to spontaneous improvement in lifestyle choices (Kip *et al*., 2002; West *et al*., 2003). For example, the occurrence of a heart attack or stroke in an immediate family member did not lead to self-initiated, sustained change in modifiable risk factors in young adults (Kip *et al*., 2002). Among low-income, rural African–American women who had not had mammogram recently, knowledge of family history of breast cancer was not associated with perceived risk or screening (West *et al*., 2003). These results argue that counseling and education are needed to actively intervene in people with a family history of common chronic disease, where the opportunities for prevention are substantial (Tavani *et al*., 2004a,b; Slattery *et al*., 2003).

Genetic counseling ensures the opportunity to provide informed consent, including discussion of the potential benefits, risks, and limitations of genetic risk assessment. Knowledge of genetic susceptibility to a common chronic disease has the potential to improve diagnosis, management, and prevention efforts. Psychological benefits can also result from knowledge of a genetic risk (Lerman *et al*., 1996; Croyle *et al*., 1997). Confirming a suspected genetic risk can be empowering and may relieve anxiety related to not knowing. In some cases, genetic risk assessment can also reassure individuals for whom a familial susceptibility can be excluded. On the other hand, potentially harmful psychological effects, such as increased anxiety, can result from knowing of a genetic risk, particularly if there are no proven interventions available for management or prevention, or if such interventions are inaccessible or unacceptable (e.g., prophylactic oophorectomy for a woman who has

not completed childbearing). Family dynamics may change from knowledge of a genetic risk for disease. For example, a parent may feel guilt about passing on a disease predisposition, or a sibling for whom genetic susceptibility has been excluded may experience survivor guilt if the susceptibility is identified in another sibling. Family members may experience loss of privacy when asked to share their medical history and medical records, and if labeled as having a genetic risk for disease, family, friends, or society may stigmatize them. There is also the possibility of misuse of genetic risk information by third parties such as employers, educators, and insurers that could exclude individuals from employment or educational opportunities, or from obtaining health, life or disability insurance, although the evidence of genetic discrimination against otherwise healthy individuals is minimal (Billings *et al*., 1992; Geller *et al*., 1996; Epps, 2003). These potential harms should be considered and weighed against the potential benefits when providing genetic risk assessment.

3.2. Pedigree analysis

Pedigree analysis is typically the first step in genetic risk assessment and diagnosis. The pedigree structure is created and usually includes all first- and second-degree relatives, spanning 3–4 generations. Demographic information for each family member is documented that typically includes each relative's current age or age at death. Medical history is documented for each family member, including age at diagnosis, cause of death if deceased, and known interventions or procedures, which can help clarify a diagnosis. For example, questioning regarding coronary artery bypass surgery, angioplasty, heart transplant, or pacemaker placement may help clarify a relative's diagnosis of heart disease. Information is also collected regarding important risk factors for a disease, such as use of hormone replacement therapy or chest irradiation for breast cancer, and smoking, asbestos exposure, and coal mining for lung cancer. Medical records are reviewed when possible to verify the medical history of each family member or at least those who are critical to the genetic risk assessment and diagnosis. The family history should include ethnicity and country of origin of grandparents since certain conditions might be more prevalent in certain ethnic groups. For example, the prevalence of insulin resistance is high among individuals of Native American admixture (Arnoff *et al*., 1977) and Asian Indian origin (Sharp *et al*., 1987), and there are common *BRCA* gene founder mutations in Ashkenazi Jewish families with breast and ovarian cancer (Struewing *et al*., 1997).

Once this information is collected, pedigree analysis is performed to determine the most likely mode of inheritance (i.e., Mendelian versus multifactorial) and the risk of disease to the patient and to unaffected relatives based on their position in the pedigree. This analysis also helps to elucidate the differential diagnosis through pattern recognition (Scheuner *et al*., 2004). For example, when considering an inherited form of breast cancer, there are at least seven different Mendelian disorders to consider, including hereditary site-specific breast cancer, hereditary breast–ovarian cancer syndrome, Li–Fraumeni syndrome, Cowden syndrome, Peutz–Jeghers syndrome, hereditary nonpolyposis colon cancer, and ataxia telangiectasia (Hoskins *et al*., 1995; Scheuner *et al*., 2004). The types of cancers

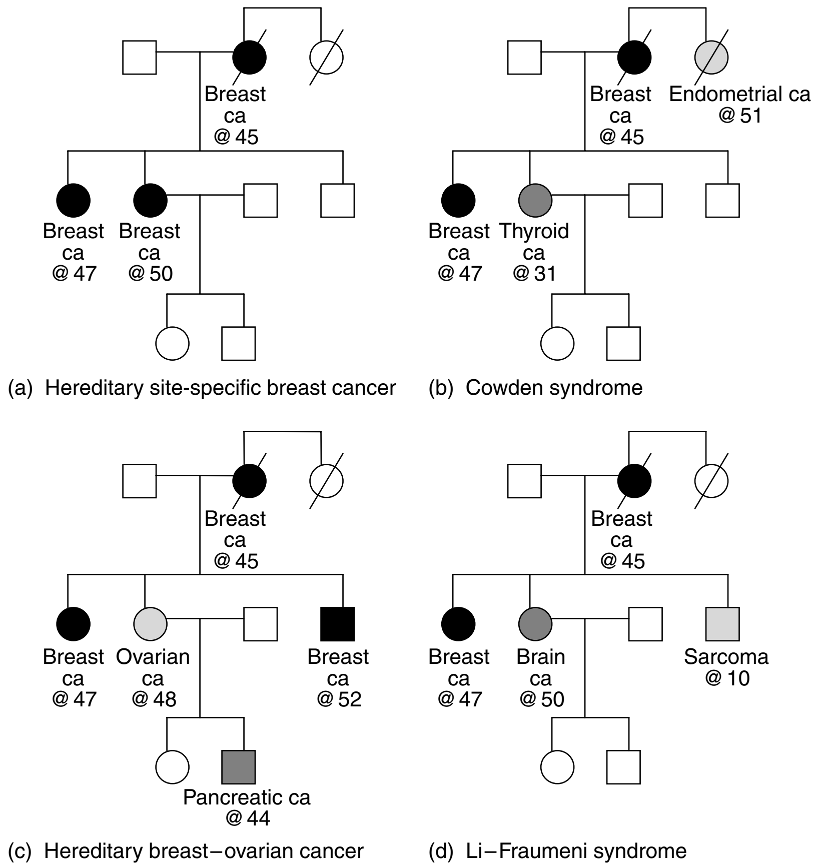

Figure 2 Each pedigree shown has a high familial risk for breast cancer. However, by recognition of the patterns of cancer in the family, a more accurate diagnosis can be made. Pedigree (a), which features early onset breast cancer and no other cancers is most consistent with hereditary site-specific breast cancer, which is often due to *BRCA1* or *BRCA2* gene mutations. Pedigree (b) features early onset breast, thyroid and endometrial cancer and is most consistent with Cowden syndrome due to *PTEN* gene mutations. Pedigree (c) features early onset breast and ovarian cancer and is most consistent with hereditary breast–ovarian cancer syndrome, which is almost always due to *BRCA1* or *BRCA2* gene mutations. In this case, a *BRCA2* gene mutation is likely given the family history of male breast cancer and pancreatic cancer. The history of early onset breast cancer, brain tumor, and childhood sarcoma in pedigree (d) is most consistent with Li–Fraumeni syndrome due to *TP53* gene mutations. Multiple primary cancers are common among individuals with Li–Fraumeni syndrome

and other conditions reported in the family help distinguish each of these syndromes (Figure 2). Mutations in different genes underlie the genetic susceptibility in these syndromes and genetic testing can help to confirm a suspected diagnosis.

For pedigrees consistent with multifactorial inheritance or that lack convincing evidence of Mendelian inheritance, quantitative risk assessment can be performed for specific conditions using mathematical models or published estimates (Amos *et al*., 1992; Claus *et al*., 1993, 1994; St John *et al*., 1993). For example, a

woman's absolute risk for breast cancer by age 80 or in the next 10 years can be provided on the basis of the family history of breast or ovarian cancer in first- and second-degree relatives and their age at diagnosis (Claus *et al*., 1993, 1994), and she can contrast this to the population risk of breast cancer by age 80 or in the next 10 years. Because family history is often the most significant predictor of risk, these models provide good estimates of risk. However, most estimates using these models have limitations, and they should not be the only means for risk assessment. In particular, most do not account for significant exposures or behaviors that might influence disease risk.

3.3. *Personal history*

In addition to review of past medical history and medical records for confirmation, assessment of signs and symptoms of the disease of concern should be performed to more accurately assess risk for the patient. For example, when evaluating a genetic risk for heart disease, review of systems should include questions regarding angina, shortness of breath, dyspnea on exertion, paroxysmal nocturnal dyspnea, pedal edema, claudication, and exercise tolerance. In the case of risk assessment for colorectal cancer, questions should be asked regarding frequency of bowel movements, caliber of the stool, color of the stool, and presence of blood in the bowel movement. If symptoms are present, follow-up confirmatory testing should be recommended. For example, exercise treadmill testing or echocardiogram to evaluate cardiovascular symptoms, or colonoscopy to assess change in bowel habits, or blood in the stool.

3.4. *Physical examination*

The physical examination should be performed to identify signs of the disease of concern as well as characteristic manifestations of Mendelian forms of a disease. For example, an evaluation for cardiovascular risk should include auscultation of the heart, lungs, and major vessels in the neck, abdomen, and groin, and palpation of the aorta and distal pulses. Any abnormalities can be followed up with additional studies, such as ultrasound. Blood pressure in the upper and lower extremities can identify hypertension, and these measurements can be used to calculate the ankle/brachial blood pressure index (ABI). Values <0.9 are correlated with atherosclerosis. Weight and height should be obtained and body mass index should be calculated to identify overweight and obese patients, and follow-up measurements can help monitor diet and exercise interventions. Waist circumference should be obtained, as increased values are associated with the metabolic syndrome (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001), a common cause of cardiovascular disease (Park *et al*., 2003). Evaluation of possible lipid disorders should include examination of the eyes, assessing corneal arcus and lipemia retinalis. Examination of the skin should include assessment for xanthelasma and tendonous xanthomas. Physical signs of Mendelian disorders that feature cardiovascular disease should

be assessed, such as dolichostenomelia and arachnodactyly associated with Marfan syndrome, abnormal scarring, and translucent skin associated with Ehlers–Danlos syndrome type IV, papular skin lesions and plaques in flexural creases and angioid streaks on the retina associated with pseudoxanthoma elasticum, and angiokeratomas (vascular cutaneous lesions), and corneal and lenticular opacities associated with Fabry disease.

3.5. Genetic testing

Identification of appropriate tests that may be helpful in confirming a genetic diagnosis and refining genetic risk is the initial step in the genetic testing process. Genetic tests for assessing common diseases usually include DNA-based tests and biochemical tests. DNA-based testing is typically performed when assessing a Mendelian form of cancer susceptibility, whereas biochemical testing is more often available to assess a susceptibility to cardiovascular disease or diabetes (Scheuner *et al*., 2004).

Most commercial laboratories performing DNA-based testing utilize polymerase chain reaction (PCR)-based methods to amplify the patient's DNA to be followed by sequencing or other methodologies. In most cases, sequencing is considered the gold standard for identification of a mutation. However, even sequencing may miss rearrangements or large deletions of DNA or mutations in regulatory regions (Yan *et al*., 2000; Gad *et al*., 2001). Rarely, errors may occur with sample handling, contamination by airborne particles in the laboratory, or failure of the PCR technique.

When considering genetic testing, clinicians should choose the testing strategy that would be most informative for a patient and their family members. Ideally, genetic testing should begin in an affected family member to identify the specific genetic determinant(s) of disease susceptibility and to recommend appropriate management. If an abnormality or abnormalities are identified, then at-risk relatives can be tested for those familial factors. Normal results can provide reassurance regarding disease risk due to those factors; however, there will always be a background or population risk for disease development. At-risk relatives with abnormal results can begin surveillance and prevention activities appropriate for their risk.

It is not always possible to test an affected family member, as they are often deceased and therefore unable to provide a sample, or not interested in testing, or unable to participate because of financial reasons. In this case, unaffected family members may participate in testing. Identification of a genetic risk factor or factors may help with the risk assessment and in planning appropriate screening and preventive strategies. Though unaffected individuals can initiate the testing process, normal test results cannot be entirely reassuring since the available clinical testing is not comprehensive. A normal test result can exclude the genetic risk factors that have been tested but not the possibility of an inherited susceptibility. In such a case, medical management would typically depend upon the empirical risks associated with the family history. To further clarify the situation, testing additional family members, both affected and unaffected, may be helpful.

Once a genetic testing strategy has been formulated, laboratories that can provide the testing are identified. Obtaining, processing, and shipping the sample may also be necessary, as well as facilitation of the billing process (providing the most appropriate diagnostic codes and documenting medical necessity for testing when requested). Issues to consider when choosing a laboratory include methodology, analytic sensitivity and specificity, technical support, cost, and turn-around time. Understanding which methodology is used is important since standards for many genetic tests currently do not exist. There is great variability in testing procedures for many conditions. As a result, clinicians need to be personally familiar with a given laboratory's protocol and the test limitations.

An individual's genetic test results should be interpreted within the context of their family history. The interpretation should incorporate a discussion of the impact of the results on their risk assessment, diagnosis, and plans for management and prevention. Family members who might benefit from risk assessment and genetic testing should also be identified, and the clinician should facilitate communication between the index case and at-risk relatives as well as provide referrals to genetics professionals or other specialists for relatives.

Interpretation of genetic test results for disease susceptibility alleles should consider the variable effects of an allele. For example, polymorphisms in the methylenetetrahydrofolate reductase (MTHFR) gene are associated with cardiovascular disease, neural tube defects, and unexplained recurrent embryo losses in early pregnancy (Isotalo *et al*., 2000; Eikelboom *et al*., 1999). The apolipoprotein E genotypes contribute to serum cholesterol differences in the population and have been associated with cardiovascular disease risk as well as risk for Alzheimer disease (Wilson *et al*., 1996; Farrer *et al*., 1997). Recognizing these associations has important implications regarding informed consent when offering specific tests for the purpose of refining a diagnosis or for presymptomatic detection of disease.

3.6. Management and prevention

Identifying individuals with genetic susceptibilities to common chronic diseases may have profound implications not only for their health but the health of their family. Knowledge of a genetic risk can influence the clinical management and prevention of a disease. Prevention strategies include targeted lifestyle changes, screening at earlier ages, more frequently and with more intensive methods than used for average risk individuals, use of chemoprevention, and for those at highest risk, prophylactic procedures and surgeries (see Table 3 for examples). Screening and prevention guidelines are available for many chronic disorders (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001; Diabetes Prevention Program Research Group, 2002; Straus *et al*., 2002; Walsh and Terdiman, 2003; Smith *et al*., 2002; Scheuner *et al*., 2004), and data are accumulating regarding the effectiveness of these strategies in high-risk individuals (Järvinen *et al*., 2000; Rebbeck *et al*., 1999, 2002; Narod *et al*., 1998, 2000). Because many behavioral risk factors for disease aggregate in families, a family-based approach to risk factor modification ought to be an effective strategy, and this has been demonstrated in a few studies (Knutsen and Knutsen, 1991; *British*

Table 3 Examples of early detection and prevention strategies according to familial risk level

Colorectal cancer

Low familial risk: Beginning at age 50, annual FOBT and/or flexible sigmoidoscopy every 5 years, or double-contrast barium enema every 5 to 10 years, or colonoscopy every 10 years (Winawer *et al*., 1997; Rex *et al*., 2000; Smith *et al*., 2001; US Preventive Services Task Force, 2002b).

Intermediate familial risk: Beginning at age 40, annual FOBT and/or flexible sigmoidoscopy every 5 years, or double-contrast barium enema every 5 to 10 years, or colonoscopy every 10 years (Winawer *et al*., 1997; Rex *et al*., 2000).

High familial risk: Beginning at age 40 or 10 years before the earliest age of diagnosis in the family, colonoscopy every 3 to 5 years (Rex *et al*., 2000). Consider daily use of aspirin (Baron *et al*., 2003; Sandler *et al*., 2003), and daily intake of supplemental folic acid 400 mcg (Giovannucci *et al*., 1998) and calcium 1200 mg (Holt *et al*., 1998; Baron *et al*., 1999).

Coronary heart disease

Low familial risk: Beginning at age 45 for women and at age 35 for men, screen for lipid disorders every 5 years or shorter intervals for people with lipid levels close to those warranting therapy (US Preventive Services Task Force, 2001).

Intermediate familial risk: Beginning at age 20 for women and men, screen for lipid disorders every 5 years or shorter intervals for people with lipid levels close to those warranting therapy (US Preventive Services Task Force[a], 2003). Consider use of aspirin daily or every other day (US Preventive Services Task Force[a], 2003).

High familial risk: Beginning at age 20 for women and men, screen for lipid disorders every 5 years or shorter intervals for people with lipid levels close to those warranting therapy (US Preventive Services Task Force[a], 2001). Assess emerging risk factors (e.g., homocysteine, lipoprotein(a), C-reactive protein, LDL cholesterol density) (Scheuner, 2003). Consider early detection strategies (e.g., carotid artery duplex scanning to measure intima-media thickness, ankle-brachial index, electron beam CT to detect coronary artery calcification) (Smith *et al*., 2000; Scheuner, 2003). Consider use of aspirin daily or every other day (US Preventive Services Task Force[a], 2002a).

[a]Based on United States Preventive Services Task Force recommendations for individuals with increased risk.
For all individuals, regardless of familial risk level, assess relevant exposures, lifestyle choices and habits, and recommend changes if indicated. Consider referral for a genetic evaluation for individuals with high familial risk.

Medical Journal, 1994; Pyke *et al*., 1997). Lifestyle changes, such as dietary modification, weight control, and smoking cessation are likely to be more effective when delivered to the family than to an individual because family members can influence each other and provide ongoing support to one another.

The plan for management and prevention should be tailored to an individual's genetic risk while taking into consideration their personal medical history, family history, habits, and preferences. Other disease risks that may influence decision making regarding options for risk reduction should be identified as part of the management and prevention plan. For example, use of tamoxifen for breast cancer prevention might be contraindicated, given a personal or family history of thrombophilia. In addition, as with any treatment plan, potential risks or complications that may result from the recommended management and prevention strategies must be recognized.

Finally, the recommendation for management and prevention options specific to an individual's genetic risk should be communicated in writing, so the patient and referring physician can incorporate these recommendations into a plan for future health management. Plans for continued contact or follow-up with a geneticist may

be appropriate to review the individualized plan for management of genetic risk, and updated personal and family history information can be obtained with revision of the management and prevention plan as indicated. New information and technology available for genetic risk assessment or management and prevention of disease can also be discussed.

Specialist Review

Current approaches to prenatal screening and diagnosis

Paula C. Cosper

University of Alabama at Birmingham, Birmingham, AL, USA

1. Introduction

Prenatal diagnosis of genetic disorders was first accomplished in 1966 when Steele and Breg performed chromosome studies on cells from an unborn fetus obtained from the amniotic fluid. Since that time, the number of disorders diagnosable prenatally has grown exponentially. Today, several methods are available for screening and detection of genetic disorders in the unborn fetus.

The most common reasons for prenatal diagnosis are:

1. maternal age 35 or over
2. previous child with a chromosome abnormality
3. parent, a known carrier of a rearrangement of chromosomes
4. family history of a detectable biochemical abnormality
5. mother, a known carrier of an X-linked disorder
6. family history of an inherited disorders detectable by ultrasound
7. abnormal first- or second-trimester screen.

Physicians who care for pregnant women should obtain information regarding any family history of genetic disorders or learning problems. Patients with a positive family history should be referred to a medical geneticist for evaluation, counseling, and possible testing. There are also screening tests that should be offered to patients of particular ethnic backgrounds. Jewish individuals, especially of Ashkenazi background, should be offered a panel of testing including Tay-Sachs disease, cystic fibrosis, Canavan's disease, and familial dysautonomia; some centers include additional tests in this panel. Caucasians should be offered screening for cystic fibrosis. Individuals of African-American descent should have sickle cell screening. Asian, Mediterranean, and Middle Eastern individuals are at increased risk for thalassemia and should be screened using a complete blood count (MCV, MCH, and hemoglobin) to determine if further testing is indicated.

2. Noninvasive screening

2.1. Second trimester

Noninvasive screening such as ultrasound and a maternal serum screen for Down syndrome, neural tube defects (NTDs), and trisomy 18 should be offered to all pregnant women regardless of family history or age. Maternal serum screening is routinely performed between 14 and 20 weeks gestation. Either three or four different analytes associated with pregnancy are measured in the maternal serum. The triple screen examines the level of alpha fetoprotein (AFP), unconjugated estriol (uE3), and human chorionic gonadotrophin (HCG) in the maternal serum. The quad screen adds Inhibin A. To take into account population differences in the screen components and laboratory differences in assay methods, the results are expressed as multiples of the median (MOM). Each laboratory that performs the testing has determined levels of each of these components for each week of pregnancy in hundreds of women who had a normal pregnancy and calculated median values for each week of pregnancy. The patient's value is compared to the median for the appropriate week of gestation and expressed as multiples of that median. Since the median values may vary significantly from week to week, it is essential that the correct gestational age be given for the patient being screened. Also taken into account in the calculation of risks from the screen are the patient's age, race, and weight. Multiple fetuses can make the screen much less accurate in predicting Down syndrome and trisomy 18. Women who receive a positive screen should be referred for further genetic testing. It should be emphasized to the patient that the maternal marker screen is not a diagnostic test, but only an estimate of risk.

AFP is a protein produced by the fetal liver and is excreted normally into the amniotic fluid through the fetal urine. If there is an opening that allows fetal fluids to escape into the amniotic fluid, the concentration of AFP will be much higher than normal in the fluid and thus in the maternal serum. Any maternal serum AFP value of 2.5 MOM or above is considered positive for open NTDs. Since insulin-dependent diabetic patients are at increased risk to have babies with NTDs, the cut-off for a positive screen in diabetic mothers is 2 MOM. The maternal serum AFP will detect at least 80% of the cases of open neural tube defects. If combined with a detailed ultrasound scan, the detection rate increases to at least 95% for open spina bifida and 100% for anencephaly. For individuals who have a family history of a first- or second-degree relative with a neural tube defect, maternal serum AFP at 16 weeks and a detailed ultrasound scan at 18 weeks are recommended. Folic acid taken before and during pregnancy has been shown to reduce the risk of having a child with a neural tube defect by 75% (Nussbaum *et al*., 2001) Since 95% of babies with neural tube defects are born to individuals with no family history of NTDs, it is recommended that all women of childbearing age take folic acid supplementation of at least 400 μg daily and higher for women who have a positive family history of NTDs. Maternal serum AFP is elevated by abnormalities other than NTDs. Abdominal wall defects and kidney problems such as congenital nephrosis can cause elevated levels of maternal serum AFP. The most commonly seen abdominal wall defects are omphalocele and gastroschisis. An ultrasound

scan can usually distinguish between these two defects. Placental problems are a common cause of elevated maternal serum AFP. When placental problems allow fetal blood to get into the maternal circulation, the levels of AFP can be greatly elevated. Fetal death and twins may also elevate serum AFP. Elevated maternal serum AFP in the absence of fetal abnormalities is associated with an increased risk for preeclampsia and premature delivery.

Maternal serum HCG and uE3 are more predictive of an increased risk for Down syndrome and trisomy 18. Both HCG and uE3 are hormones produced by the placenta. HCG is the strongest predictor of Down syndrome. An elevation in the maternal serum level of HCG will almost always increase the risk of Down syndrome in the fetus over the normal maternal age risk. Fetuses with Down syndrome are also typically associated with a low AFP and low uE3. When the values of all three components of the screen are low, there is an increased risk for trisomy 18. The maternal serum triple screen will detect at least 60% of the fetuses with Down syndrome and 50% of the fetuses with trisomy 18 with a 5% false-positive rate (Wapner *et al*., 2003). Very low levels of uE3 may be associated with steroid sulfatase deficiency (X-linked ichthyosis) or the Smith–Lemli–Opitz syndrome (Nussbaum *et al*., 2001).

Inhibin A is now a part of the maternal serum screen in many laboratories. Inhibin A is a hormone produced by the granulosa cells of the female follicles and also by the placenta. It inhibits the synthesis and secretion of FSH and LH by the pituitary. Inhibin A may be elevated in the maternal serum if the fetus has Down syndrome. The addition of Inhibin A to the triple screen, thus making it the quad screen, increases the detection rate of Down syndrome to 80% (Malone *et al*., 2003).

2.2. *First trimester*

Screening for chromosome abnormalities and other birth defects may be done at 11–13 weeks of pregnancy, with a combination of ultrasound and biochemical markers in the maternal serum. An ultrasound scan is performed to measure the nuchal translucency (NT), which is the area of translucency between the skin and underlying tissue at the base of the neck of the fetus. An increase in the NT is caused by an accumulation of fluid under the skin. Fetuses with an increased NT are more likely to have genetic problems or other birth defects such as cardiac abnormalities. Measuring the NT requires special training and experience to obtain consistent results, and quality control is a major issue with this technology. The first-trimester screen also includes the determination of the level of free beta HCG and pregnancy-associated placental protein A (PAPP-A) in the maternal serum. High amounts of free beta HCG and low levels of PAPP-A are associated with an increased risk for the fetus to have Down syndrome. Low levels of both free beta HCG and PAPP-A are associated with an increased risk of trisomy 18 in the fetus. Using a mathematical formula taking into consideration the NT measurement, maternal serum levels of free beta HCG and PAPP-A, gestational age, and maternal age, the risk for Down syndrome, and trisomy 18 can be calculated. Multicenter studies in the United States have indicated that at least 80% of the fetuses with

Down syndrome can be identified using this technology. The false-positive rate is about 5%. The screening identified about 90% of the cases of trisomy 18 with a false-positive rate of 2% (Malone *et al*., 2003; Malone and D'Alton, 2003). First-trimester evaluation of nasal bones does not add significantly to the detection of Down syndrome (Malone and D'Alton, 2003). One limitation of the first-trimester screen is the lack of testing for neural tube defects. It is recommended that patients who have first-trimester screening have a maternal serum alpha fetoprotein and targeted ultrasound in the second trimester for the detection of neural tube defects.

2.3. *Integrated screen*

The integrated screening that combines both first-trimester nuchal translucency plus serum screening and second-trimester quad screening appears to be the most efficient testing method with almost a 90% detection rate for Down syndrome with a false-positive rate of 5% (Malone *et al*., 2003). A major drawback to this approach is that the results would not be available to the patient until about the 16th week of pregnancy.

2.4. *Ultrasound*

Ultrasound has become a very important noninvasive tool for prenatal diagnosis of certain fetal abnormalities. The high resolution of today's ultrasound machines allows detection of many types of birth defects. We have just discussed its use in screening for fetal aneuploidy in the first trimester of pregnancy and the detection of fetal abnormalities such as neural tube defects and abdominal wall defects. There are a number of single-gene disorders that are associated with abnormalities that can be detected by ultrasound including Holt–Oram syndrome, Meckel–Gruber syndrome, Beckwith–Weideman syndrome, osteogenesis imperfecta, and many types of dwarfism. Multifactorial disorders such as cleft lip and heart defects may also be detected. Certain findings on ultrasound such as hydrops, cystic hygroma, polydactyly, diaphragmatic hernia, ventriculomegaly, duodenal atresia, and renal abnormalities may warrant further testing such as amniocentesis since those abnormalities may be associated with a chromosome abnormality.

3. Invasive testing

3.1. *Chorionic villus sampling*

For diagnostic testing, we must obtain cells representative of the fetus using the technique of chorionic villus sampling (CVS) or amniocentesis. The most common reasons for diagnostic testing are maternal age of 35 or above and abnormal first- or second-trimester screening tests. The procedure used most commonly in the first trimester is chorionic villus sampling. This procedure may be done either trans-abdominally or transcervically. The position of the placenta can determine which

approach is used. The transabdominal approach involves the insertion of a 22-gauge spinal needle through the abdomen into the placenta and aspiration of a sample of tertiary villi. For the transcervical approach, a flexible cannula is introduced through the cervix to the placenta where the villi are aspirated. The tissue sampled in CVS is tertiary villi. The villi are derived from the extraembryonic cells of the blastocyst called the trophoblast. Since these cells are from extraembryonic tissue, there may be instances where abnormalities present in these cultured cells may not represent the fetus. About 1–2% of the patients who have CVS are recommended to have a follow-up amniocentesis because of some ambiguous result (usually mosaicism). There is also a greater risk for maternal cell contamination in CVS since the maternal decidua is so closely associated with the chorionic villi. Laboratory personnel must be very diligent in cleaning the sample of any contaminating decidua. The major advantage of CVS is that it can be performed in the 10th to 12th week of pregnancy, thus giving a result earlier than the second-trimester testing. Neural tube defects cannot be detected with CVS, so second-trimester screening with maternal serum AFP and ultrasound are recommended. Fetal loss rate after CVS is about 1%. Amniocentesis may be done during the first trimester, but usually not until the 12th week. Early amniocentesis has a miscarriage risk of about 2% and has been associated with an increased risk for club foot in the fetus (Canadian Early and Mid-Trimester Amniocentesis Trial (CEMAT) Group, 1998).

3.2. Amniocentesis

The preferred method of obtaining fetal cells for prenatal diagnosis in the second trimester is the amniocentesis. It most commonly is done between 16 and 18 weeks. An ultrasound scan is performed before the amniocentesis to verify the number of fetuses and viability, look for structural abnormalities in the uterus, determine the position of the placenta and the best position to introduce the needle for removal of fluid, and examine the fetus for any abnormalities. The procedure involves the removal of amniotic fluid from the amniotic sac with a 22-gauge spinal needle. It is done transabdominally under ultrasound guidance. In experienced hands, the fetal loss rate after amniocentesis is 1in 300–400. Fortunately, most women do not have any problems following the procedure. The most common complaint is mild cramping, which usually subsides within a few hours after the tap. Bleeding or leakage of amniotic fluid vaginally may occur in about 0.2% of the cases (Brumfield *et al*., 1996).

The amniotic fluid contains cells from the fetus that can be cultured and used for cytogenetic, biochemical, or molecular testing. The amniotic fluid itself may be used to test for certain abnormalities. At least 99% of the neural tube defects can be detected by assaying the amniotic fluid for AFP (Milunsky, 1986). As discussed previously, the amount of AFP is elevated in the amniotic fluid when there is an opening such as a neural tube defect or abdominal wall defect. Other causes of an elevated amniotic fluid AFP include fetal death, congenital nephrosis, and the presence of fetal blood.

Cytogenetic, biochemical, and molecular testing usually take from 1 to 3 weeks to complete. Using the fluorescence in situ hybridization (FISH) technique, there

is now a quick screen for trisomy 13, 18, 21 and detection of the number and type of sex chromosomes. By using DNA probes for these chromosomes, abnormalities in number for these chromosomes can be detected within 24 h after obtaining the amniotic fluid sample and is 98–99% accurate in detecting those abnormalities. This is particularly useful if the pregnancy is advanced and a quick result is needed. This study does not detect any structural abnormalities or changes in chromosome number involving any of the other chromosomes. A full cytogenetic study is recommended, and no decision about pregnancy termination should be based on the FISH result alone.

3.3. Periumbilical blood sampling (PUBS)

Occasionally, it is necessary to obtain a fetal blood sample for diagnosis. To do this, a procedure similar to an amniocentesis is performed and a small amount of blood is taken from the umbilical cord. Since the fetal loss rate after PUBS is 2–3%, it is used only when CVS or amniocentesis cannot provide the information needed (Nussbaum *et al*., 2001). Some situations that might warrant PUBS include decreased amount of amniotic fluid, ambiguous results from an amniocentesis or CVS procedure that may be clarified by studying fetal blood, or diagnosis of an abnormality that cannot be done from any other tissue.

3.4. Preimplantation genetics

Recent advances in genetics and reproductive technologies have made it possible to determine for some abnormalities the genetic makeup of an embryo before introduction into the uterus. This allows the implantation of only the unaffected embryos. Preimplantation genetic diagnosis (PGD) starts with routine in vitro fertilization. At the 6–8-cell blastocyst stage of the embryo, one or two cells are removed for genetic testing. These cells are then analyzed using polymerase chain reaction (PCR) or FISH to detect the abnormality of interest. Using FISH, PGD can detect chromosome abnormalities such as aneuploidies, deletions, translocations, and other rearrangements. Candidates for PGD using FISH include:

1. Women who are over 35 and at increased risk to have babies with aneuploidy.
2. Couples where one carries a rearrangement of chromosomes or deletion such as the DiGeorge syndrome deletion on chromosome 22.
3. Women who carry an abnormal X-linked gene where there is no molecular testing available (for sex determination).

Couples who are carriers of a detectable recessive, dominant, or X-linked disorder may elect to have PGD using the PCR technology. This, of course, requires a definitive diagnosis and known mutations in the parents. Obtaining PCR results from one cell is a daunting task and requires a great deal of experience and care in the laboratory.

There are many advantages of PGD. Having the diagnosis made before implantation takes away the necessity of making a decision about termination of a pregnancy

when an abnormality is detected during the first or second trimester of pregnancy. Individuals who are known carriers of a genetic disease will sometimes decide not to have children to avoid passing the abnormal gene to them. PGD affords these people the opportunity to have children free of the disease. As PGD becomes a more widely used technology, the incidence of these serious detectable diseases potentially will decline.

The disadvantages in PGD lie mainly in the technology of the procedures required to accomplish it. Normally fertile women must undergo IVF procedures in order to get pregnant. The technical difficulty of embryo biopsy, PCR, and FISH on a single cell may cause problems or failure of the process. Not all chromosome or single gene disorders can be detected by PGD because only a certain number of chromosomes or genes may be examined during one process. Many ethical concerns have been raised about the possible use of the technology and the fate of the unused embryos.

In the future, it is possible that comparative genomic hybridization (CGH) may be used to analyze all the chromosomes in the complement rather than a selected few. Also, the technique of interphase conversion where an interphase nucleus is converted to metaphase by fusing it with an enucleated oocyte may allow the analysis of all chromosomes.

3.5. Fetal cells in maternal serum

It was demonstrated over 35 years ago that fetal cells exist in maternal serum (Walknowska *et al*., 1969). Since that time, investigators have been trying to develop technologies to concentrate enough fetal cells from the maternal serum for prenatal diagnostic testing. Limited success has been reported. At this point, no consistent, effective protocols are available for prenatal diagnosis using these cells. Research in this area is continuing.

Specialist Review

Advances in newborn screening for biochemical genetic disorders

Inderneel Sahai and Harvey L. Levy
Harvard Medical School, Boston, MA, USA

1. Introduction

Newborn screening (NBS) has evolved significantly since its introduction in 1962 for one biochemical genetic disorder, phenylketonuria (PKU). It now includes endocrinopathies, hemoglobinopathies, congenital infections, cystic fibrosis, and congenital deafness as well as many biochemical genetic disorders. The wide coverage of biochemical genetic disorders has been possible because of the recent addition of tandem mass spectrometry (MS/MS) to the technology of newborn screening. This article briefly reviews newborn screening and then focuses on the advances in neonatal identification of the biochemical genetic disorders.

2. Background

Soon after Robert Guthrie developed newborn screening as a means of preventing mental retardation in PKU, he realized that several other biochemical genetic disorders fit the same mold, that is, the disorders are capable of producing mental retardation but are potentially preventable by newborn identification and dietary treatment. Among these disorders were homocystinuria, maple syrup urine disease (MSUD), and galactosemia - disorders that can also result in somatic complications. Consequently, he modified his bacterial assay for phenylalanine, the analytical marker for PKU, to render it responsive to increases in other metabolites and to allow for the detection of these disorders (Guthrie, 1968).

The keys to these additions and further developments in newborn screening are the dried blood filter paper specimen, now known as the Guthrie specimen, and the small amount of blood needed for the assays. Consequently, tests can be added to newborn screening without the requirement for another specimen, provided the test can be performed on whole blood eluted from a small disk punched from the specimen. Over the years, many investigators have become aware of the possibility that this system could be used to screen newborns for disorders in their areas of interest, and several have succeeded in modifying existing assays to meet the specifications of newborn screening. The results have been newborn screening

for congenital hypothyroidism (Dussault *et al*., 1975), sickle cell disease (Garrick *et al*., 1973), and congenital adrenal hyperplasia (Pang *et al*., 1977). However, until very recently, the only biochemical genetic disorder among these additions has been biotinidase deficiency (Heard *et al*., 1984).

This omission was not by choice. Guthrie and his group tried in vain to expand biochemical genetic coverage. Several programs adopted neonatal urine screening using paper or thin-layer chromatography to expand coverage (Bamforth *et al*., 1999). This resulted in additional coverage but required collection of the specimen at several weeks of age rather than within the first day of life and examined only amino acids and a very limited number of organic acids. Consequently, many serious disorders were not covered, or not covered in time for effective therapy, and the disorders that were most frequently identified were benign (Wilcken *et al*., 1980). Thus, coverage of many important biochemical genetic disorders by screening the newborn blood specimen had to await MS/MS technology.

3. Overview of tandem mass spectrometry (MS/MS)

The mass spectrometer is an analytical instrument that detects ions by virtue of their mass and charge. It has been used for many years to identify metabolites that are separated on columns in techniques such as capillary electrophoresis, gas chromatography, and HPLC. This requirement for prior separation of metabolites, however, meant that mass spectrometry could not be used in screening since separation would be much too time consuming for the rapid throughput that routine screening requires. However, MS/MS is applicable to newborn screening because it directly analyzes the individual components of complex mixtures, eliminating the need for prior chemical separation. Developed in the late 1970s (McLafferty, 1981), MS/MS employs two mass spectrometers in tandem separated by a collision cell. It takes advantage of the principle that molecules fragment into predictable species depending on their structural properties. Millington *et al*. (1990) adapted this technology to identify metabolites in the Guthrie dried blood spots (DBS) of newborn infants. Naylor subsequently used this system to greatly expand the number of biochemical genetic disorders identifiable in routine newborn screening (Naylor and Chace, 1999).

In its current application to newborn screening, MS/MS measures amino acids and acylcarnitine conjugates of organic and fatty acids in the Guthrie blood specimen. Figure 1 depicts the elements of MS/MS and the chemical characteristics of derivatization and fragmentation of the amino acids and the acylcarnitines. For a detailed description of the MS/MS methods and analysis, the reader is referred to articles by Chace *et al*. (1999, 2002, 2003). The process of newborn screening begins with methanol extraction of blood from the specimen, followed by butanol derivatization of amino acids and acylcarnitines. The butyl ester derivatives are ionized by electrospray. The ions enter the first MS, where the parent molecules are sorted by mass and charge and are then directed into the collision chamber. In this chamber, collision-induced disassociation (CID) produces characteristic fragments because of collision between an inert gas and the ionized particles. These fragments are then guided into the second MS where they are sorted by mass and charge (m/z)

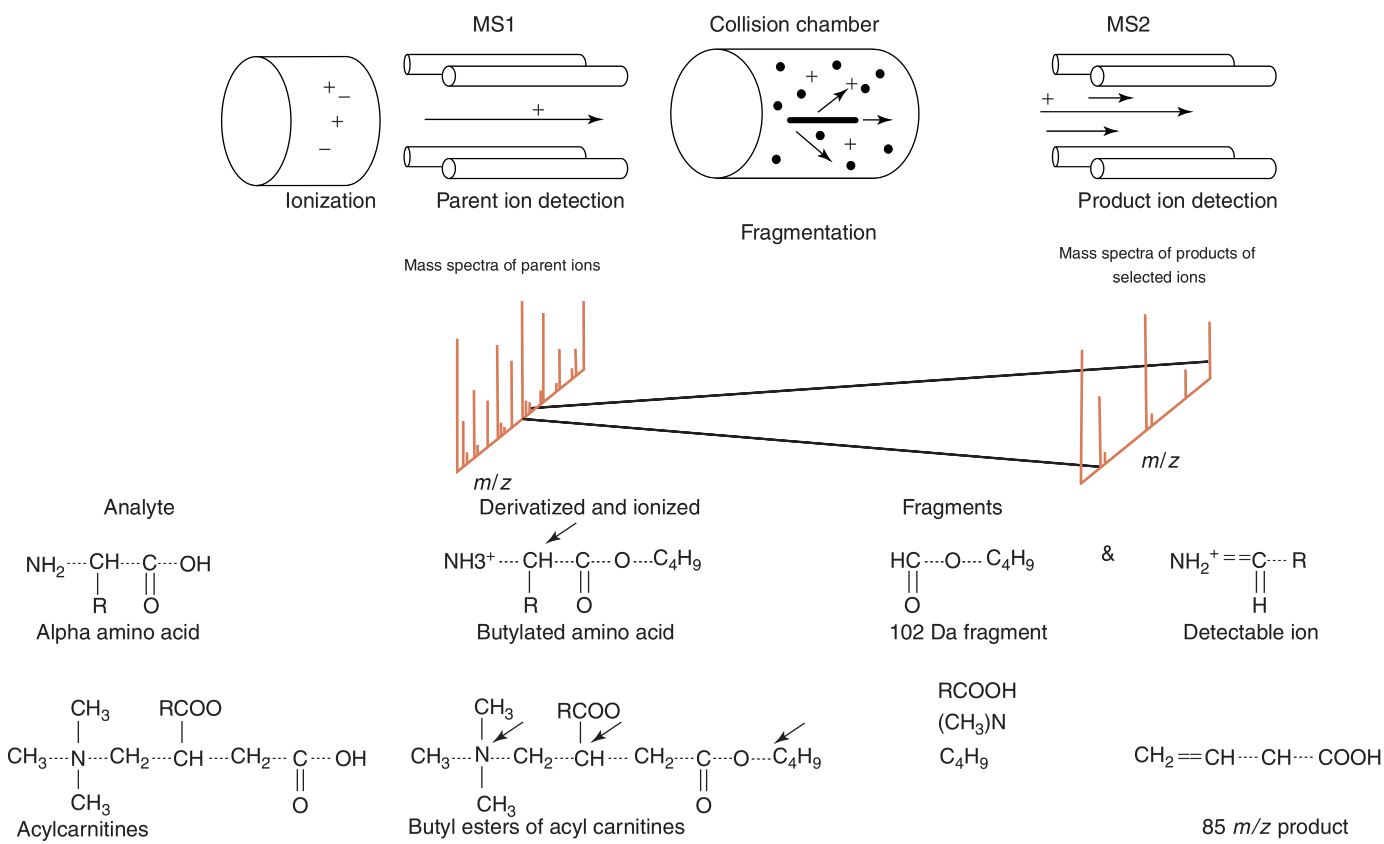

Figure 1 Schematic diagram of a tandem mass spectrometer and the path of the molecules and ions. Depicted below the diagram is the spectrum obtained from MS1 and MS2, which is later correlated by the analyzer. Also shown are amino acid and acylcarnitine molecules and their fragments

and detected as signals. Computer algorithms enable correlation between the mass spectra of the fragments in the second MS and the spectra of the intact parent molecules in the first MS. The data thus acquired can be scanned for characteristic fragments so that parent molecules corresponding with these fragments can be selectively analyzed. In general, amino acids are identified by their loss of a 102-Da fragment, while acylcarnitines are always identified by the presence of their common m/z 85 fragment ion. Different scanning modes can analyze the same data for other specific fragments, thereby resulting in identification of multiple classes of compounds in the same specimen. Quantitative analysis is performed using the ratio of the metabolite to its isotopic analog (internal standard is added at the beginning of the process). Software programs are formatted to analyze the spectra, perform the calculations to determine the concentrations, and flag the abnormal values. Though the automated system detects metabolite abnormalities, personnel familiar with metabolic disorders are essential for recognizing the metabolite profiles that indicate a disorder.

MS/MS analysis requires only about 2 minutes per specimen, making it ideal for high-volume programs such as newborn screening. Nevertheless, the system has certain technical limitations: (1) The equipment needs proper maintenance and tuning, making trained technicians vital for its operation. (2) The volume of blood used in calculating the metabolite values is the volume assumed to have been extracted from the standard-sized disk of the Guthrie specimen used in the analysis, but the actual volume can vary in different specimens, depending on the extraction efficiencies. This probably accounts for most of the variation seen with MS/MS analysis. (3) The derivatization can produce hydrolysis of acylcarnitines, falsely reducing the estimate of its endogenous quantity (and falsely increasing the estimated level of endogenous carnitine).

4. Expanded newborn screening

This is the term generally applied to the increased number of biochemical genetic disorders identifiable in newborn screening that is made possible by MS/MS technology. They are broadly classified into amino acid, organic acid, and fatty acid oxidation disorders.

4.1. Prevalence

The reported frequency of identified cases in expanded newborn screening has varied from 1:2400 among 250,000 screened infants in Baden-Württemberg, Germany (Schulze *et al*., 2003) to 1:4000 among 1.1 million infants who were screened primarily in Pennsylvania (Chace *et al*., 2002) and 1:5000 among 164,000 of those who were screened in Massachusetts (Zytkovicz *et al*., 2001). In New South Wales, Australia, a frequency of 1:6400 cases among 362 000 screened infants has been reported, but it excludes PKU (Wilcken *et al*., 2003), one of the most frequent of the detected disorders.

4.2. Amino acid disorders

This group of disorders is marked by the accumulation of characteristic amino acids; each disorder is the result of an inherited defect in an enzyme that is responsible for conversion of an amino acid into its product. Disorders traditionally screened, such as, PKU, MSUD, and homocystinuria, plus disorders that were not previously screened, such as, tyrosinemia, hyperglycinemia, hydroxyprolinemia, and several urea cycle defects, are identifiable by MS/MS. The incidence of the amino acid disorders detected by MS/MS screening has been reported as 1:3800 in Germany (Schulze *et al*., 2003), 1:7400 in Pennsylvania (Chace *et al*., 2003), and approximately 1:8000 in Massachusetts (Zytkovicz *et al*., 2001).

The clinical phenotype of the amino acid disorders is usually insidious in development. In PKU, for instance, the neonate is clinically normal and remains so until developmental delay, irritability, and autistic features appear during the latter half of the first year. Homocystinuria may present with a similar picture, subsequently producing somatic features that include ectopia lentis, skeletal changes, and thromboembolism. Tyrosinemia type I can produce liver disease in early infancy, whereas tyrosinemia type II can produce developmental delay without liver involvement. MSUD, however, can cause profound neonatal disease characterized by metabolic acidosis. This phenotype is characteristic of the organic acid disorders (in which category MSUD is often included). Other exceptions are the urea cycle disorders, in which the affected neonate may have severe hyperammonemia, producing lethargy that can rapidly progress to coma. Nevertheless, in all of the amino acid disorders, clinical signs of disease may not have appeared during the first few days of life. Expanded newborn screening, revealing a specific amino acid elevation, can identify these infants and preventive therapy can be effective.

The major confirmatory test following any newborn screening abnormality is a plasma amino acid analysis. Table 1 lists the amino acid disorders that can be identified in expanded screening according to the screening abnormalities that bring them to attention and highlights their biochemical and clinical phenotypes.

4.3. Fatty acid oxidation disorders (FAOD)

Fatty acid oxidation primarily occurs in the mitochondria and is critical for energy generation in the fasting state or during exercise. The sequence of fatty acid oxidation from transport into mitochondria through β-oxidation is depicted in Figure 2. It begins with the mobilization of very long chain and long chain fatty acids from adipose tissue. In the cytosol of cells, they link to coenzyme A (CoA) under the influence of fatty acyl-CoA synthetase to yield fatty acyl-CoA. The fatty acyl-CoA moves to the mitochondrion, as does carnitine, which has entered the cell via a carnitine transporter. On the outer mitochondrial membrane, carnitine palmitoyltransferase I (CPT I) catalyzes an exchange of carnitine with the CoA to yield fatty acylcarnitine, releasing CoA. The fatty acylcarnitine is transported to the inner mitochondrial membrane by a translocase where CPT II decouples and

Table 1 Amino acid disorders

Major screening analyte(s)	Disorder	Enzyme defect	Clinical phenotype	General treatment
Phenylalanine	Phenylketonuria (PKU)	Phenylalanine hydroxylase	Mental retardation	Dietary restriction of phenylalanine
			Autism Hyperactivity Seizures	
Leucine/isoleucine/ hydroxyproline	Maple syrup urine disease (MSUD)	Branched-chain a-ketoacid dehydrogenase complex	Lethargy	Dietary restriction of branched-chain amino acids
			Failure to thrive Coma Seizures Maple syrup odor in urine and cerumen	
Leucine/isoleucine/ hydroxyproline	Hydroxyprolinemia	Hydroxyproline oxidase	Asymptomatic	None
Methionine	Homocystinuria	Cystathionine β-synthase	Mental retardation	Dietary restriction of methionine
			Arachnodactyly	Supplemental B6 (for B6 responsive)
			Osteoporosis Ectopia lentis Thromboembolism	
Methionine	Hypermethioninemia (MAT I/III deficiency)	Methionine adenosyl transferase (MAT I/III)	Asymptomatic	None known
			(Possibly rare cognitive reduction)	

Tyrosine	Tyrosinemia type I	Fumarylacetoacetate hydrolyase	Hepatic disease	2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC); dietary restriction of phenylalanine and tyrosine
			Hypoglycemia Hypophosphatemic rickets	Liver transplant
Tyrosine	Tyrosinemia type II	Tyrosine aminotransferase	Keratoconjunctivitis	Dietary restriction of phenylalanine and tyrosine
			Palmer/plantar keratosis Cognitive reduction	
Citrulline	Citrullinemia	Argininosuccinic acid synthetase	Hyperammonemia	Dietary restriction of protein
	(Urea cycle defect)		Mental retardation Failure to thrive Lethargy, coma	Supplements: L-arginine Sodium benzoate Sodium phenylacetate
Citrulline	Argininosuccinic acidemia (Urea cycle defect)	Argininosuccinic acid lyase	Hyperammonemia Failure to thrive Lethargy, coma	Dietary restriction of protein Supplements: L-arginine Sodium benzoate Sodium phenylacetate
Arginine	Arginase deficiency	Arginase	Mild-moderate hyperammonemia	Dietary restriction of arginine and protein
	(Urea cycle defect)		Mental retardation Spastic diplegia	
Glycine	Nonketotic hyperglycinemia (NKH)	Glycine cleavage enzyme	Seizures	Supportive care
			Hypotonia Marked lethargy	Sodium benzoate

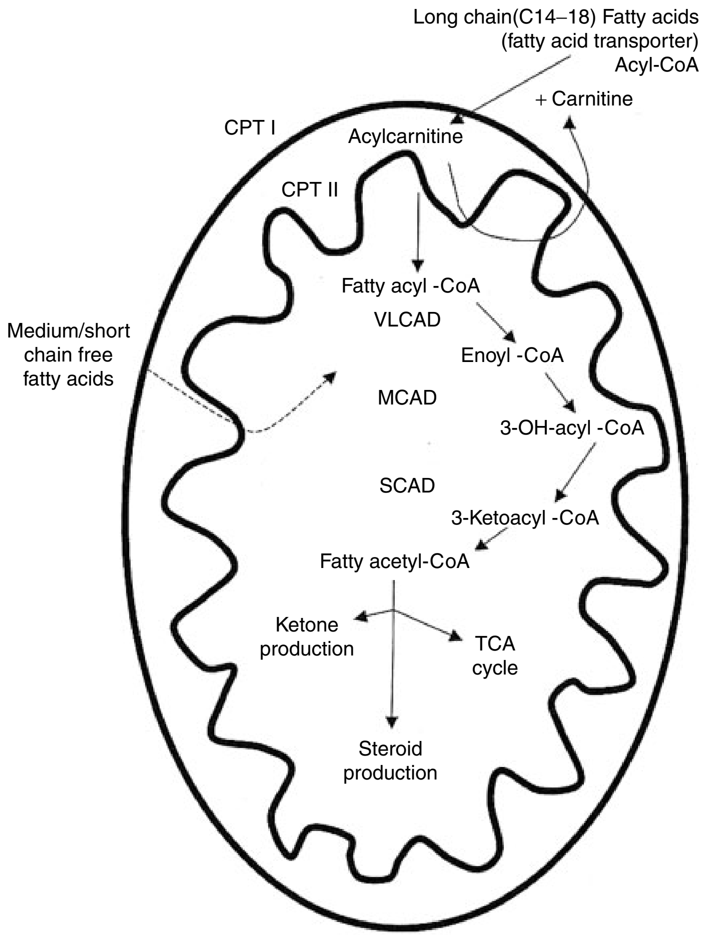

Figure 2 Metabolism of fatty acids illustrating entrance into mitochondrion and intramitochondrial β-oxidation. Abbreviations: CPT, Carnitine palmitoyltransferase; VLCAD, very long chain acyl-CoA dehydrogenase; MCAD, medium chain acyl-CoA dehydrogenase; SCAD, short chain acyl-CoA dehydrogenase; TCA, tricarboxylic acid

releases the carnitine and links the fatty acid to CoA again. The resulting fatty acyl-CoA moves into the mitochondrial matrix where it is β-oxidized sequentially by six enzymes, including very long chain acyl-CoA dehydrogenase (VLCAD), long chain hydroxyacyl-CoA dehydrogenase (LCHAD), medium chain hydroxyacyl-CoA dehydrogenase (MCHAD), medium chain acyl-CoA dehydrogenase (MCAD), short chain hydroxyacyl-CoA dehydrogenase (SCHAD), and short chain acyl-CoA dehydrogenase (SCAD). The successive removal of two carbons via the β-oxidation cycle results in acetyl-CoA that is used to generate energy through the TCA cycle and the synthesis of ketones. Acetyl-CoA is also required for the synthesis of steroids.

Disorders have been described for each of these transporters and enzymes except fatty acyl-CoA synthetase. The reported frequency of the FAODs in expanded newborn screening is 1:10 000 in Germany (Schulze *et al*., 2003) and Massachusetts (Zytkovicz *et al*., 2001), and 1:13 000 in Australia (Wilcken *et al*., 2003). The most frequently detected in expanded newborn screening has been medium chain acyl-CoA dehydrogenase deficiency (MCADD), with an incidence of 1:20 000, which is similar to that for PKU.

The most striking clinical feature in the FAOD phenotype is intolerance to fasting or to vigorous exercise. Normally, reduction of glucose in the fasting state or the requirement for additional glucose during exercise triggers the compensatory production of ketones to supply energy. In the FAOD, the inability to meet this requirement for energy through the β-oxidation of fatty acids results in muscle weakness; lethargy; fatty liver; inhibition of gluconeogenesis, exacerbating the hypoglycemia; and a high risk of sudden death. Cardiomyopathy is a particular feature of carnitine transporter defect and of defects in the β-oxidation of very long chain and long chain fatty acids. A key laboratory feature is hypoketotic hypoglycemia. Other laboratory findings during acute episodes include metabolic acidosis, hyperammonemia, and elevations of the liver enzyme levels. Early detection by expanded newborn screening combined with treatment that includes avoidance of fasting, adherence to a low-fat diet, and carnitine supplementation has been effective in preventing sudden death and other complications in these disorders (Waisbren *et al*., 2003).

In expanded newborn screening by MS/MS, the carnitine and acylcarnitine patterns reveal the presence of an FAOD and, usually, the specific defect. Since carnitine transport defect limits both the transport of free carnitine from the intestinal lumen and its reabsorption in the kidneys, the blood carnitine concentration is very low. In CPT-I deficiency, acylcarnitines are not formed, so the concentration of free carnitine is high but that of the acylcarnitines are low. In CPT-II deficiency, the acylcarnitines are unchanged, so the long chain acylcarnitine levels are increased. For the β-oxidation defects, the levels of long chain acylcarnitines are increased in very long chain acyl-CoA dehydrogenase deficiency (VLCADD), long chain hydroxyacylcarnitines levels are increased in long chain hydroxyacyl-CoA dehydrogenase deficiency (LCHADD), medium chain acylcarnitines, particularly octanoylcarnitine (C8), are increased in MCADD, and the short chain acylcarnitines, primarily butyrylcarnitine (C4), are increased in short chain acyl-CoA dehydrogenase deficiency (SCADD). After an acylcarnitine abnormality has been ascertained, usually by repeat screening, confirmatory testing is performed by analyses of plasma acylcarnitines and urine acylglycines. The individual fatty acid oxidation disorders are summarized in Table 2.

In contrast to amino acid concentrations, which increase in a time-dependent manner, the acylcarnitines decrease significantly with passage of time and with initiation of feeding. This occurs within the first week of life. The rate of decrease of the long chain acylcarnitines is more rapid than that of the short chain acylcarnitines (Chace *et al*., 2003). Effective screening, therefore, requires collection of the Guthrie specimen within 24–48 h of life and lowering of the cutoff value for repeat specimens. The concentrations of multiple acylcarnitine markers and relative molar ratios are also important in the interpretation of a positive result.

Table 2 Fatty acid oxidation disorders

Major screening analyte(s)	Disorder	Enzyme defect	Clinical phenotype	General treatment
C4 (butyrylcarnitine)	Short chain acyl-CoA dehydrogenase deficiency (SCADD)	Short chain acyl-CoA dehydrogenase (SCAD)	Variable presentation: may be asymptomatic	Avoid fasting
				Diet: low fat, high carbohydrate (CHO)
C8 (octanoylcarnitine)	Medium chain acyl-CoA dehydrogenase deficiency (MCADD)	Medium chain acyl-CoA dehydrogenase (MCAD)	Asymptomatic when well	Avoid fasting
			With fasting and/or illness: vomiting, lethargy, seizures, coma, hypoketotic hypoglycemia, metabolic acidosis, hepatomegaly	Frequent CHO feedings (q4 hours until 4 months; q6 hours until 8 months; q8 hours thereafter)
			Can cause sudden death	Possible supplementation with carnitine
C8 (octanoylcarnitine)	Multiple acyl-CoA dehydrogenase deficiency (MADD)	Multiple acyl-CoA dehydrogenation defects due to decreased electron transfer flavoprotein (ETF), or decreased electron transfer flavoprotein ubiquinone oxidoreductase (ETF-Q0)	Hypoketotic hypoglycemia	Avoid fasting
	[Also known as glutaric acidemia II (GA II)]		Metabolic acidosis	Dietary restriction of fat
C8:1 (octenoylcarnitine)			"Sweaty feet" odor	Frequent CHO feedings
			Muscle weakness	Supplement with riboflavin and carnitine
			Neonatal form has occasional dysmorphic features and hypotonia	
C14 (tetradecanoylcarnitine)	Very long chain acyl-CoA dehydrogenase deficiency (VLCADD)	Very long chain acyl-CoA dehydrogenase (VLCAD)	Variable presentation:	Avoid fasting
			Cardiomyopathy (hypertrophic)	Low fat, high CHO diet

C14:1 (tetradecenoylcarnitine)			Sudden death	Frequent CHO feedings, medium chain triglycerides (MCT)
			With illness: vomiting, lethargy, seizures, coma	Carnitine
			Hypoketotic hypoglycemia	
C16OH (hydroxydecanoylcarnitine)	Long chain hydroxyacyl-CoA dehydrogenase deficiency (LCHADD)	Long chain hydroxyacyl-CoA dehydrogenase (LCHAD)	Hypoketotic hypoglycemia	Avoid fasting
			Mild hyperammonemia	Low fat, high CHO diet
C18:1OH (hydroxyoctadecenoylcarnitine)			Cardiomyopathy	Supplement with carnitine
			Sudden death	
C18OH (hydroxyloctadecanoylcarnitine)			Associated maternal syndrome	Early severe hypotonia
			Renal tubular acidosis	Hemolysis, Elevated liver enzymes and Low Platlets (HELLP)
CN (carnitine)	Carnitine palmitoyltransferase I (CPT I) deficiency	Carnitine palmitoyltransferase I (CPT I)	Infantile form:	Dietary restriction of high fat foods
			Fasting hypoketotic hypoglycemia	Supplement: Frequent CHO feedings, MCT supplements, carnitine
			Lethargy	
			Hepatomegaly	
			Seizures	
C16 (palmitoylcarnitine)	Carnitine palmitoyltransferase II (CPT II) deficiency	Carnitine palmitoyl-transferase II (CPT II)	Infantile presentation:	Dietary restriction of high fat foods
	or	or	Hypoketotic hypoglycemia	Supplement: Frequent CHO feedings, carnitine
C18:1 (octadecenoylcarnitine)	Carnitine/acylcarnitine translocase deficiency	Carnitine/acylcarnitine translocase	Lethargy	
			Seizures	
			Cardiomyopathy	

Table 3 Organic acid disorders

Major screening analyte	Disorder	Enzyme defect	Clinical phenotype	General treatment
C3 (propionylcarnitine)	Propionic acidemia	Propionyl-CoA carboxylase	Metabolic acidosis	Dietary restriction of threonine, isoleucine, valine, methionine
			Hyperammonemia Vomiting Failure to thrive	
C3 (propionylcarnitine)	Methylmalonic acidemia	Methylmalonyl-CoA mutase	Metabolic acidosis	Dietary restriction of isoleucine, valine, methionine (supplemental B_{12} for B_{12}-responsive form)
			Hyperammonemia Vomiting Failure to thrive	
C5 (isovalerylcarnitine)	Isovaleric acidemia	Isovaleryl-CoA dehydrogenase	Metabolic acidosis "Sweaty feet" odor	Dietary restriction of leucine Supplemental glycine and L-carnitine
			Vomiting Lethargy Failure to thrive	
C5 (2-methylbutyrylcarnitine)	2-methylbutyryl-CoA dehydrogenase deficiency	2-methylbutyryl-CoA dehydrogenase	Possibly Asymptomatic	Dietary restriction of protein
		(short/branched-chain acyl-CoA dehydrogenase)	Possibly Failure to thrive, hypoglycemia, metabolic acidosis	Supplementation with L-carnitine

C5DC (glutarylcarnitine)	Glutaric Acidemia I	Glutaryl-CoA dehydrogenase	Dystonia	Dietary restriction of lysine and tryptophan
			Acidosis and vomiting	Supplemental L-carnitine, riboflavin
			Macrocephaly	
C5OH (3-hydroxyisovalerylcarnitine)	3-Hydroxy-3-methylglutaryl (HMG)-CoA lyase deficiency	3-Hydroxy-3-methylglutaryl-CoA lyase	Vomiting	Intravenous (IV) glucose
			Lethargy Hypotonia Seizures Hypoglycemia Metabolic acidosis	Restrict protein, fat
C5OH (3-hydroxyisovalerylcarnitine)	3-Methylcrotonyl-CoA carboxylase (3-MCC) deficiency	3-Methylcrotonyl-CoA carboxylase	Asymptomatic, or:	IV glucose
			Lethargy Hypotonia Hypoglycemia Metabolic acidosis	Restrict protein

4.4. Organic acid disorders (OAD)

The defect in an OAD is usually in an enzyme within an amino acid degradative pathway that is responsible for conversion of an organic acid derivative of the amino acid to another organic acid. The result of the defect is an increased concentration of the unconverted organic acid, some of which can conjugate with free carnitine to produce an increased acylcarnitine level detectable by MS/MS. The reported frequency of OADs is 1:15 000 in Germany (Schulze *et al*., 2003), 1:30 000 in Australia (Wilcken *et al*., 2003), and 1:55 000 in Massachusetts (Zytkovicz *et al*., 2001). The unconjugated organic acid (and secondary organic acid metabolites) accumulate to very high levels and produce metabolic acidosis. This can present in the neonate as poor feeding, lethargy, vomiting, tachypnea, and seizures. During such acute episodes, substantial hyperammonemia is also often present. Later complications include developmental delay, mental retardation, and other neurologic abnormalities. A notable exception to this dramatic presentation is glutaric acidemia type I (GA I), in which the neonate appears to be normal (except for macrocephaly) but suddenly becomes dystonic later in the first or second year of life, often during an acute febrile illness or after an immunization. Expanded newborn screening by MS/MS has identified these neonates presymptomatically by an acylcarnitine abnormality and has improved their outcome through appropriate dietary therapy (Waisbren *et al*., 2003). Confirmation of an acylcarnitine screening abnormality that suggests an OAD includes urine organic acid analysis. The individual organic acid disorders are summarized in Table 3.

5. Considerations in MS/MS screening

5.1. Amino acid disorders

MSUD: An elevation of levels of leucine and variable increases in levels of valine, isoleucine, and alloisoleucine are the characteristics of MSUD. Leucine, isoleucine, and alloisoleucine have the same molecular weight and, therefore, give the same signal in the MS/MS analysis. Nevertheless, since all these metabolites are elevated in MSUD, an increase in the signal intensity of "leucine", especially when accompanied by increased valine levels, is suggestive of this disorder. The false-positive rate for MSUD can be reduced by considering the ratios of "leucine" to phenylalanine and "leucine" to alanine. Increased levels of hydroxyproline also increases the signal intensity of "leucine" since its molecular weight is the same as leucine and the isoleucines. Consequently, hydroxyprolinemia, which is a benign disorder (Kim *et al*., 1997), can suggest MSUD in MS/MS screening. An important difference, however, is the likely presence of increased valine levels in MSUD and normal valine levels in hydroxyprolinemia.

Homocystinuria: Homocystinuria results in a primary elevation of homocysteine levels, with a secondary increase in methionine. Homocysteine cannot be detected by MS/MS, so methionine is the marker metabolite for this disorder.

As a secondary metabolite, however, the accumulation of methionine lags behind that of homocysteine. Consequently, during the first days of life, the methionine level can remain normal or below the cutoff level for identifying it as being abnormal even if the infant has homocystinuria (Peterschmitt *et al*., 1999). This is especially likely when the Guthrie screening sample is collected at less than 24 hours after birth.

Tyrosinemias: Tyrosinemia I results in only a moderate elevation of tyrosine. Thus, in order to increase the sensitivity of the screening, a low threshold for identifying increased tyrosine must be set. Nevertheless, since many or most affected infants have normal blood tyrosine levels during the first days of life, they are still missed. This was recognized several years ago in Quebec and the newborn screening program was stimulated to apply an enzyme assay screening method for succinylacetone, the specific marker metabolite for tyrosinemia I, to the Guthrie specimen (Grenier *et al*., 1982), resulting in almost complete ascertainment. Unfortunately, succinylacetone is currently not identifiable by MS/MS. Tyrosinemia II may more likely be identified on the basis of increased tyrosine. When increased tyrosine is flagged in newborn screening, the vast majority of infants have transient neonatal tyrosinemia, a benign finding (Wilcken *et al*., 2003).

Urea cycle defects: Three of the five urea cycle disorders (i.e., citrullinemia, argininosuccinic acidemia, and arginase deficiency) can be identified by expanded newborn screening. Citrullinemia and argininosuccinic acidemia are identified on the basis of increased citrulline levels, more pronounced in citrullinemia than in argininosuccinic acidemia. Arginase deficiency is identified by increased arginine levels. The other two urea cycle disorders, carbamyl phosphate synthetase deficiency (CPSD) and ornithine transcarbamylase deficiency (OTCD), could be determined by decreased citrulline levels, but, at present, this identification is limited by an excessively high false-positive rate.

5.2. *Fatty acid oxidation disorders*

MCADD: The levels of the primary analyte of MCADD, octanoylcarnitine (C8), can also be elevated because of valproate therapy or medium chain triglycerides (MCT) oil supplementation and is also an indicator of the fatty acid disorder multiple acyl-CoA dehydrogenase deficiency (MADD). The C8/C10 ratio, which is usually elevated in MCADD, is useful in distinguishing MCADD from these other causes of elevated C8. MCADD is also usually accompanied by elevations in C6, C10, and C10:1.

SCADD: Elevations in butyrylcarnitine (C4) levels, characteristic of this disorder, are also seen in the fatty acid disorder, MADD.

VLCADD: Elevations of C14 (tetradecanoylcarnitine) and C14:1 (tetradecenoylcarnitine) are the primary abnormalities of this disorder, though they can also be present in MADD, CPT-II, and carnitine-acylcarnitine translocase deficiency. VLCADD may also be accompanied by elevations of C16, C18, and C18:1.

LCHADD: Elevations of the primary analytes of LCHADD, C16OH (hydoxy-hexadecanoylcarnitine), C18OH (hydroxyoctanoylcarnitine), and C18:1OH (hydroxyoctadecenoylcarnitine), can be minimal, making LCHADD difficult to diagnose. Elevations of C16, C14, C14:1, and C14OH may also be present.

CPT-I deficiency: This is the only FAOD with elevated levels of free carnitine. Also present in CPT-I deficiency are decreased levels of C16, C18, and C18:1.

CPT-II deficiency and carnitine-acylcarnitine translocase deficiency: The levels of the primary analytes for these disorders, C16 (hexadecanoylcarnitine), C18 (octadecanoylcarnitine), and C18:1(octadecenoylcarnitine), can also be elevated in VLCADD and LCHADD but are more prominent here. Additionally, free carnitine is decreased, and the ratio of C16 to carnitine is a useful diagnostic marker.

Carnitine transporter defect: In this disorder, free carnitine level is decreased to less than 5% of normal levels.

MADD (Glutaric Acidemia II): The acylcarnitines levels are only mildly increased in MADD, making the detection of this disorder difficult. MADD is characterized by increased C8 and C8:1, but variable elevations of C6, C5, C5DC, C4, C14, and C14:1 are also seen.

5.3. *Organic acid disorders*

Propionic acidemia (PA) and methylmalonic acidemia (MMA): C3 (propionyl-carnitine) level is elevated in both these conditions, but the level is typically higher in PA. In fact, in MMA the C3 elevation may be just at or even below the screening cutoff, rendering MMA very difficult to detect. Since cobalamin (B12) is a cofactor for methylmalonyl-CoA mutase, vitamin B12 deficiency can also result in increased methylmalonic acid and C3. The ratio of C3 to C2 increases the sensitivity and specificity for detection.

Isovaleric acidemia (IVA): The indicating metabolite of isovaleric acidemia in newborn screening is C5 (isovalerylcarnitine). 2-methylbutyryl-CoA dehydrogenase deficiency (2-MBDD) also produces an elevation of C5 but is not as striking an elevation as does IVA. However, pivalic acid, a constituent of certain antibiotics, produces a metabolite that is also detected at the m/z of C5. Neonates of mothers who ingested pivalic acid can thus mistakenly be thought to have IVA or 2-MBDD on newborn screening (Abdenur *et al*., 1998).

Glutaric acidemia I (GA I): The primary analyte in this disorder, C5DC (glutarylcarnitine), a dicarboxylic acid, has two negative charges that need to be neutralized by derivatization before analysis in MS/MS. Elimination of the derivatization step can thus decrease the sensitivity for C5DC.

Hydroxymethylglutaryl (HMG) CoA lyase and 3-methylcrotonyl carboxylase (3-MCC) deficiencies:The level of the marker metabolite for these two disorders, C5OH (3-hydroxyisovalerylcarnitine), can also be elevated in 3-methylglutaconic aciduria I. Furthermore, a peak at m/z 318 indicating C5OH can also be produced by methylbutyrylhydroxy acylcarnitine, which is the marker metabolite for methyl acetoacetyl-CoA thiolase (β-ketothiolase) deficiency.

6. Missed cases

Most infants with biochemical genetic disorders are not identified by newborn screening. These infants usually have disorders that are currently not detectable by screening, including diseases in categories such as the lysosomal disorders (e.g., Gaucher disease and Pompe disease), the glycogen storage diseases (e.g., von Gierke disease), the mitochondrial disorders (e.g., Mitochondrial Encephalomyopathy, Lactic Acidosis and Stroke like episodes (MELAS), Myoclonic Epilepsy with Ragged Red Fibers (MERRF)), and others. Attempts are being made to include these categories in newborn screening, the most notable of which is the development of feasible screening methods to detect lysosomal disorders in the newborn (Chamoles *et al*., 2001), but, so far, methodologies suitable for routine screening have not emerged.

Much less frequent are infants with metabolic disorders that are identifiable by newborn screening but are undetected. These "missed" infants can be placed into two categories, true negatives and false negatives. In the former classification are infants such as those with tyrosinemia I who did not have increased tyrosine when the Guthrie specimen was collected, those with homocystinuria and a normal methionine level during screening (Wagstaff *et al*., 1991), and those with carnitine transporter defect but a carnitine level in the Guthrie specimen that was above the cutoff level for identification (Wilcken *et al*., 2003). In the false-negative category is the rare infant who had an abnormal level of the metabolite marker for a disorder but was missed because of program or laboratory error (Smith *et al*., 2001).

The important message is that any patient in whom there is clinical suspicion of a biochemical genetic disorder could have a disorder, either because it was not included in the newborn screening schedule or because it was missed in the screening process. Thus, all such patients should have laboratory testing for the disorders. These tests may include plasma amino acid analysis, urine organic acid testing, plasma acylcarnitine profiling, urine acylglycine analysis, tests for lysosomal disorders, and/or additional tests, depending on the clinical and general laboratory findings.

7. Molecular genetic techniques

The application of molecular genetic techniques to screening for a wide spectrum of disorders has been made possible by the stability of DNA in the Guthrie card (McCabe *et al*., 1987). Segments of genes can be amplified directly from the filter paper matrix using the polymerase chain reaction (PCR) without prior extraction. These amplified segments can be examined for mutations relevant to the disorder(s) screened using identification techniques such as restriction analysis or single-nucleotide polymorphism (SNP) methodology. Molecular testing is not currently used in primary newborn screening for multiple reasons, including the many mutations responsible for each of the biochemical genetic disorders, the greatly increased "noise" that would be generated by heterozygote detection, and the prohibitive expense. The plethora of mutations could be met by multiplex PCR coupled with microarrays using chip technology (Caggana *et al*., 1998),

but heterozygote detection and perhaps the expense would continue to be major issues. Nevertheless, candidates for primary molecular screening include those with treatable disorders with few molecular etiologies such as factor V Leiden, sickle cell disease, and the mitochondrial MERRF and MELAS syndromes. Primary screening for severe combined immunodeficiency (SCID), fragile X syndrome, type I diabetes, acute lymphoblastic anemia, and hereditary hemochromatosis might also be considered.

Currently, molecular testing in newborn screening is used as a second tier, through examination of Guthrie cards from infants in whom the primary screening result was abnormal. The purpose of this is to sort the affected infants from those whose primary screening abnormality was due to some reason other than the targeted disorder. The most notable use of molecular testing is in screening for cystic fibrosis, wherein the primary screen, immunoreactive trypsinogen (IRT), can be increased for many reasons other than cystic fibrosis. Second tier testing of the abnormal specimens sorts out those infants who harbor one or more CFTR mutations known to be associated with cystic fibrosis. In expanded newborn screening, second tier molecular testing is also used to test the Guthrie specimen for the A985G mutation in MCAD, the major mutation associated with MCADD, when the primary screen reveals an increased level of C8. In both these examples, second tier molecular testing substantially reduces the number of false-positive results.

8. Postmortem specimens

Inherited disorders of fatty acid oxidation account for an estimated 3–6 % of sudden unexpected deaths in infancy (Boles *et al*., 1998). Among this group, MCADD is the most frequent, and death during the initial presentation has been noted in 25–33% of the cases (Iafolla *et al*., 1994). Sudden death as a result of an inherited metabolic disorder may remain unexplained even after an autopsy and, hence, may get classified as sudden infant death syndrome (SIDS). To examine the frequency of biochemical genetic disorders in such infants and children, MS/MS analysis was performed on postmortem Guthrie specimens obtained from over 7000 cases of sudden unexplained death. In 66 specimens, diagnosis of a biochemical genetic disorder was considered likely (Chace *et al*., 2001). The disorders included MCADD, VLCADD, glutaric acidemia I and II, CPT-II/translocase deficiency, carnitine deficiency, isovaleric acidemia/2-methylbutyryl-CoA dehydrogenase deficiency, and LCHADD. This suggests that protocols should include metabolic screening by MS/MS as part of the postmortem investigation of all cases of sudden death.

Postmortem blood specimens from all infants, even those without a metabolic disorder, are characterized by increased carnitine, acylcarnitines, and amino acids. Consequently, identification of biochemical genetic disorders from postmortem specimens must utilize criteria that are different from those used for the interpretation of metabolic profiles in newborn screening.

Specialist Review

Advances in cytogenetic diagnosis

Daynna J. Wolff
Medical University of South Carolina, Charleston, SC, USA

1. Introduction

Long before the human genome project made the idea of studying genomes alluring, the original "genome screen", a karyotype, was used to detect genetic aberrations. Just three years after Tjio and Levan (1956) reported that human cells contained 46 chromosomes, Lejeune *et al*. (1959), Ford *et al*. (1959), and Jacobs and Strong (1959) described the numerical chromosome abnormalities associated with Trisomy 21, Turner syndrome, and Klinefelter syndrome, respectively. Thus, the importance of clinical cytogenetics in medical practice was established. Since the early days of assessing the number of solid-stained chromosomes, clinical cytogenetics has been, and continues to be transformed by technological advances such as high-resolution banding, fluorescence in situ hybridization (FISH), and comparative genomic hybridization (CGH). This chapter presents a short overview of clinical cytogenetics and highlights recent advances in the field.

2. Overview of clinical cytogenetics

The study of chromosomes has become standard of care for many constitutional, as well as acquired, disorders. Pregnant women over the age of 35 and those with aberrant serum screening studies or abnormal ultrasound findings are routinely offered prenatal diagnosis for chromosome disorders. Newborns with multiple congenital abnormalities, children with developmental delays or mental retardation, and couples with reproductive difficulties have chromosomal analyses as part of the routine laboratory evaluation (*see* Article 11, **Human cytogenetics and human chromosome abnormalities**, Volume 1 and Article 20, **Cytogenetics of infertility**, Volume 1). In addition, cytogenetic analysis of hematologic malignancies and solid tumors provides important information for diagnosis, prognosis, and treatment decisions (*see* Article 14, **Acquired chromosome abnormalities: the cytogenetics of cancer**, Volume 1).

Generation of a banded karyotype using traditional cytogenetic methods requires that cells be in the metaphase component of the cell cycle. Spontaneously dividing cells may be obtained directly from bone marrow, lymph nodes, and chorionic villi trophoblasts. However, cell culture, with or without mitogens, is necessary to assess

cells from amniotic fluid, solid tissues, and peripheral blood. The basic steps for obtaining cells in metaphase and preparing for cytogenetic analysis are the same for all cell types: arresting cells in metaphase by disrupting spindle fiber attachments using colcemid, swelling cells by placing in a hypotonic solution, fixing the cells using a methanol:acetic acid treatment, releasing the chromosomes from cell membrane onto slides or coverslips, and staining the chromosomes to achieve the light and dark banding patterns. Once these procedures have been performed, skilled microscope technologists and the laboratory director evaluate metaphase cells and the arranged karyotypes to assess for chromosomal aberrations. Standard karyotypic studies typically detect chromosomal abnormalities that involve approximately 5–10 Mb of DNA. High-resolution studies of cells captured in the prometaphase stage of the cell cycle can distinguish greater than 1000 separate bands and allow for the identification of alterations involving 3–5 Mb (Yunis, 1981).

Three additional methods have been particularly useful in achieving an even higher resolution, such that small alterations (<3 Mb) in DNA copy number or location can be detected. These methods are fluorescence in situ hybridization (FISH), multicolor painting/banding (SKY, M-FISH, and M-banding), and comparative genomic hybridization (CGH). These techniques enable cytogeneticists to go from the chromosomal level to the molecular level and to resolve the most complex karyotypes.

3. FISHing for abnormalities

Incorporation of FISH (also known as molecular cytogenetics) has greatly increased the sensitivity of chromosome studies (*see* Article 22, **FISH**, Volume 1). The process of FISH involves hybridization of cloned fluorochrome-labeled DNA fragments (probes) to target chromosomal sequences. Probe DNA is denatured in the presence of Cot-1 DNA that binds highly and moderately repetitive genomic sequences to allow for select hybridization of the unique sequence DNA to the target. Probe detection is accomplished by UV-light excitement of a fluorochrome, such as fluorescein-5-thiocyanate (FITC) or rhodamine that is either directly attached to the probe DNA or attached to a hapten (biotin or digoxygenin)-labeled probe.

Using FISH technology, subtle aberrations in chromosome content can be readily assessed and linked with clinical disorders. FISH has not only been used to detect submicroscopic alterations in metaphase cells, it may also be performed on interphase nuclei. Importantly, FISH probes have been mapped to chromosomal locations and molecular sequence maps, allowing for the direct connection of data being generated from the human genome project to clinical phenotypes caused by cytogenetic abnormalities. These links provide clues to the molecular basis of disease and the genes involved.

One of the first clinical applications of FISH was the development of definitive diagnostic tests for microdeletion and microduplication syndromes that result from alterations of submicroscopic amounts of genetic material, typically <2 Mb (*see* Article 17, **Microdeletions**, Volume 1). For example, FISH is routinely used to identify microdeletions of 22q11.2 in patients with DiGeorge and Velocardiofacial (VCF) syndromes (Figure 1a). Because these relatively common syndromes have

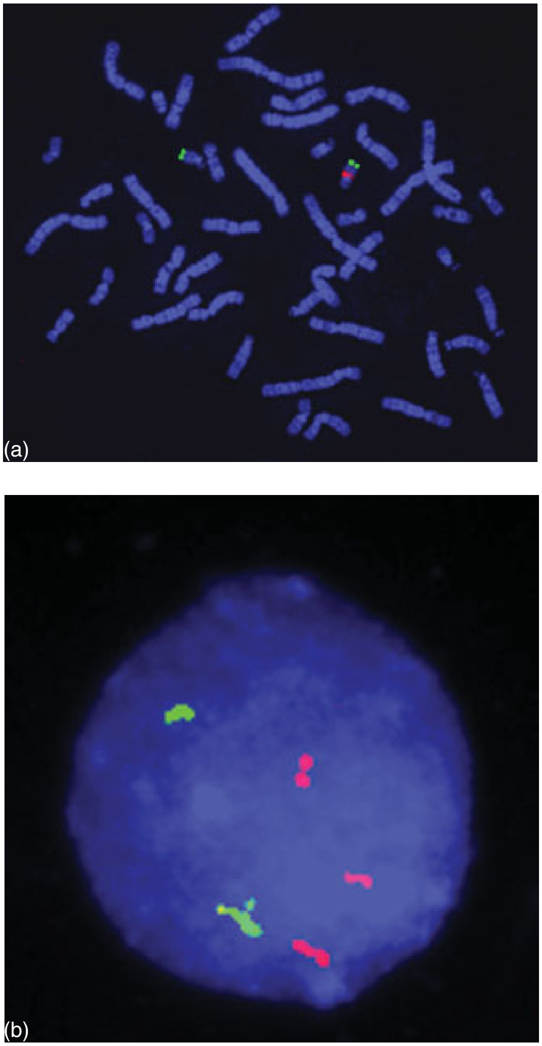

Figure 1 FISH with a probe for TUPLE1 on a metaphase cell from a patient with DiGeorge syndrome revealing a deletion of 22q11.2 (a), and on an interphase cell from a patient with Dup(22)(q11.2q11.2) syndrome (9) (b) (Figure supplied by S. Jalal, Mayo Clinic.)

relatively high frequencies, they are associated with congenital heart disease and may be inherited in a significant number of cases (Swillen *et al*., 1998), FISH studies are also performed for fetuses and newborns with a heart defect, and parents of children diagnosed with DiGeorge or VCF. The majority of the deletions, which are mediated by repetitive duplicated regions, have the same proximal and distal breakpoints (Lindsey, 2001; Lupski, 1998). The nonallelic homologous recombination events that generate deletions may also result in duplications of 22q11.2 (Figure 1b), which has been associated with dysmorphic features, growth failure, cognitive deficits, hearing loss, and velopharyngeal insufficiency

Table 1 Common genetic abnormalities in malignancies that are routinely studied using FISH

Chromosomal aberration[a]	Chromosome – gene(s) involved	Disease association
t(9;22)(q34;q11.2)	9 – *ABL*1 22 – *BCR*	Acute lymphocytic leukemia Acute myeloblastic leukemia Chronic myelogenous leukemia
t(15;17)(q22;q21.1)	15 – *PML* 17 – *RARA*	Acute myeloblastic leukemia
t(*;11)(*.*; q23)	11 – *MLL*	Acute lymphocytic leukemia Acute myeloblastic leukemia
t(8;21)(q22;q22)	8 – *CBFA2T*1 (*ETO*) 21 – *RUNX*1 (*AML*1)	Acute myeloblastic leukemia
inv(16)(p13q22) or t(16;16)(p13;q22)	16q22 – *CBFB*	Acute myeloblastic leukemia
t(12;21)(p13;q22)	12 – *ETV*6 (*TEL*) 21 – *RUNX*1 (*AML*1)	Acute lymphocytic leukemia
Trisomy 8	8 – 8*cen*	Acute lymphocytic leukemia Chronic myelogenous leukemia
t(8;14)(q24;q32)	8 – *MYC* 14 – *IGH*	Acute lymphocytic leukemia Non-Hodgkin's lymphoma
t(11;14)(q13;q34)	11 – *CCND*1 14 – *IGH*	Non-Hodgkin's lymphoma Multiple myeloma
t(14;18)(q32;q21)	14 – *IGH* 18 – *BCL*2	Non-Hodgkin's lymphoma
t(*;14)(*.*;q32)	14 – *IGH*	Non-Hodgkin's lymphoma Multiple myeloma
Del(13)(q14) or −13	Unknown tumor suppressor	Chronic lymphocytic leukemia Multiple myeloma
Trisomy 12	12 – 12cen unknown gene(s)	Chronic lymphocytic leukemia
del(11)(q23)	*ATM*	Chronic lymphocytic leukemia
HER-2 amplifaction	*ERBB*2 (*HER*2)	Breast cancer

[a] An asterisk (*) is used to delineate multiple loci or breakpoints.

(Ensenauer *et al*., 2003). FISH is also useful for studying recombination at low copy repeats resulting in deletion/duplication of 15q11.2 (Prader–Willi/Angelman/Dup(15)(q11.2q11.2) syndromes), 17p11.2 (Smith–Magenis/dup(17)(p11.2p11.2) syndromes), and 17p12 (hereditary neuropathy with liability to pressure palsies (HNPP)/Charcot–Marie–Tooth disease type 1A (CMT1A) syndromes) (Lupski, 1998).

An area that has been advanced greatly by FISH is the study of chromosomal abnormalities associated with cancer. Probes have been developed for the majority of recurrent translocations, as well as for some deletions, duplications, and amplifications found in hematologic malignancies and solid tumors (Table 1) (Wolff and Schwartz, 2004). Commercially available *BCR/ABL*1 probe sets are used to identify *BCR/ABL*1 fusion events in diagnostic samples of patients with chronic

myelogenous leukemia (CML) and are also used for posttreatment residual disease assessment. In addition, FISH is valuable for detecting the nearly 20% of CML patients with atypical FISH patterns resulting from microdeletions at the ABL1 breakpoint (Sinclair *et al*., 2000). Patients with these microdeletions have a relatively poor prognosis and reduced response to treatment (Huntly *et al*., 2001; Cohen *et al*., 2001; Smoley *et al*., 2004). As the deletions are not visible with routine cytogenetics and cannot be readily detected by polymerase chain reaction (PCR), FISH is the optimal methodology for accessing this prognostic marker.

One of the most important advantages of FISH over routine cytogenetic studies is the ability to enumerate chromosomes and to detect structural aberrations in interphase cells. For acute lymphocytic leukemia (ALL), routine cytogenetic studies often produce suboptimal results; therefore, FISH is a valuable adjunct to routine testing. Many clinical laboratories offer an ALL FISH screening panel assessment that may include probes for t(9;22) (*BCR/ABL*1), 11q23 (*MLL)*, t(12;21) (*ETV* 6/*RUNX* 1), *MYC*, and a common deletion in 9p21-22 (Andreasson *et al*., 2000; Nordgren *et al*., 2002). The panel of probes will detect the majority of genetic abnormalities associated with ALL, particularly since the screen is also useful for unmasking hidden hyperdiploidy when multiple signals are seen for various probes. In chronic lymphocytic leukemia (CLL), the disease cells have a low mitotic index; therefore, the more sensitive interphase FISH assay with a battery of probes (Figure 2) has largely replaced conventional cytogenetics (*see* Article 14, **Acquired chromosome abnormalities: the cytogenetics of cancer**, Volume 1). FISH studies reveal that the most common abnormalities include deletions of 13q14, trisomy 12, deletions of 11q22.3-q23.1, deletions of 17p13, and deletions of 6q21-q23 (Dohner *et al*., 2000). These genetic abnormalities are important independent predictors of CLL progression and survival.

FISH provides the framework for monitoring numerous loci in a single test format. One of the best examples is a probe panel used to detect subtle aberrations near the ends of chromosomes (Knight *et al*., 1997, Figure 3). Homologous recombination within repetitive telomeric regions can result in submicroscopic deletions or duplications of the adjacent unique DNA sequence (subtelomeric sequences). Because the subtelomeres are extremely gene rich (Saccone *et al*., 1992), abnormalities in these regions are likely to have clinical significance. FISH studies with probes for the subtelomeric DNA sequences that are found approximately 100–300 kb from the physical ends of the chromosomes has increased the aberration detection sensitivity for the subtelomeric sequences by at least 10-fold over conventional chromosome studies (National Institutes of Child Health and Institute of Molecular Medicine Collaboration, 1996). Abnormalities have been documented by FISH in approximately 5% of patients with idiopathic mental retardation and previous normal karyotypic analysis (Knight *et al*., 1999; Joyce *et al*., 2001; Popp *et al*., 2002). Detection rates are highest in cases with moderate to severe mental retardation (Knight *et al*., 1999) and in cases with prenatal onset of growth retardation, dysmorphic features, and/or a positive history of mental retardation (deVries *et al*., 2001).

Another widely used FISH panel, consisting of probes for chromosomes 13, 18, 21, and the sex chromosomes, identifies numerical abnormalities, as well as triploidy, in uncultured amniotic fluid cells for prenatal diagnostic studies (Klinger

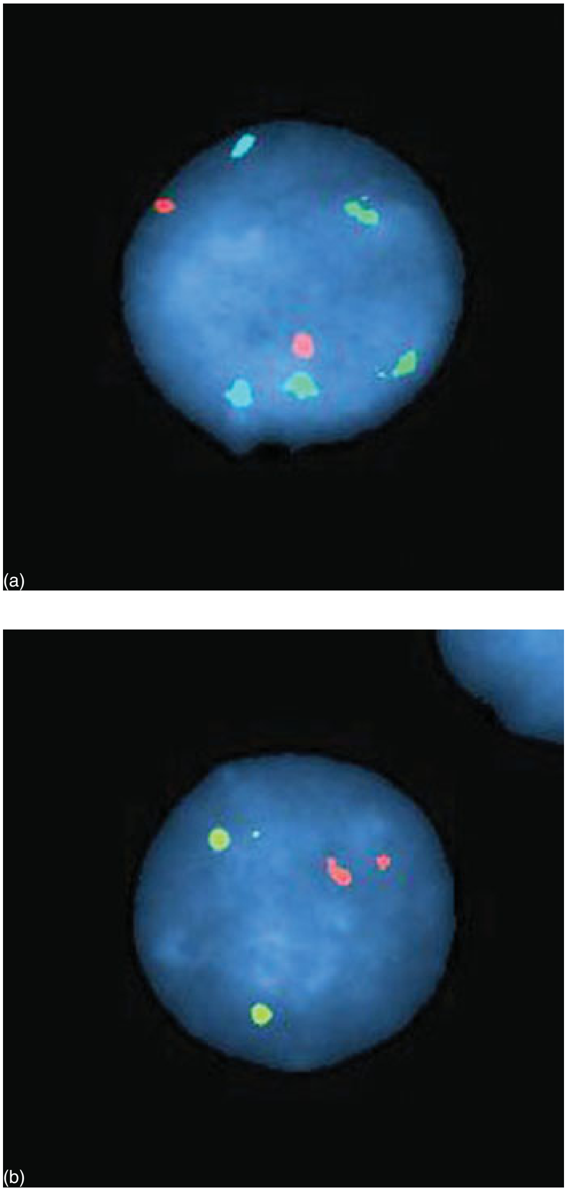

Figure 2 Results of a CLL probe panel (Vysis, Inc, Downers Grove, IL) analysis on interphase cells from a patient diagnosed with chronic lymphocytic leukemia. The analysis revealed three green signals for the probe for the centromere of chromosome 12, consistent with trisomy 12, two red and two aqua signals for the probes for 13q14 and the 13 centromere, respectively (a), two red signals for the p53 gene, and two green signals for the ATM gene (b)

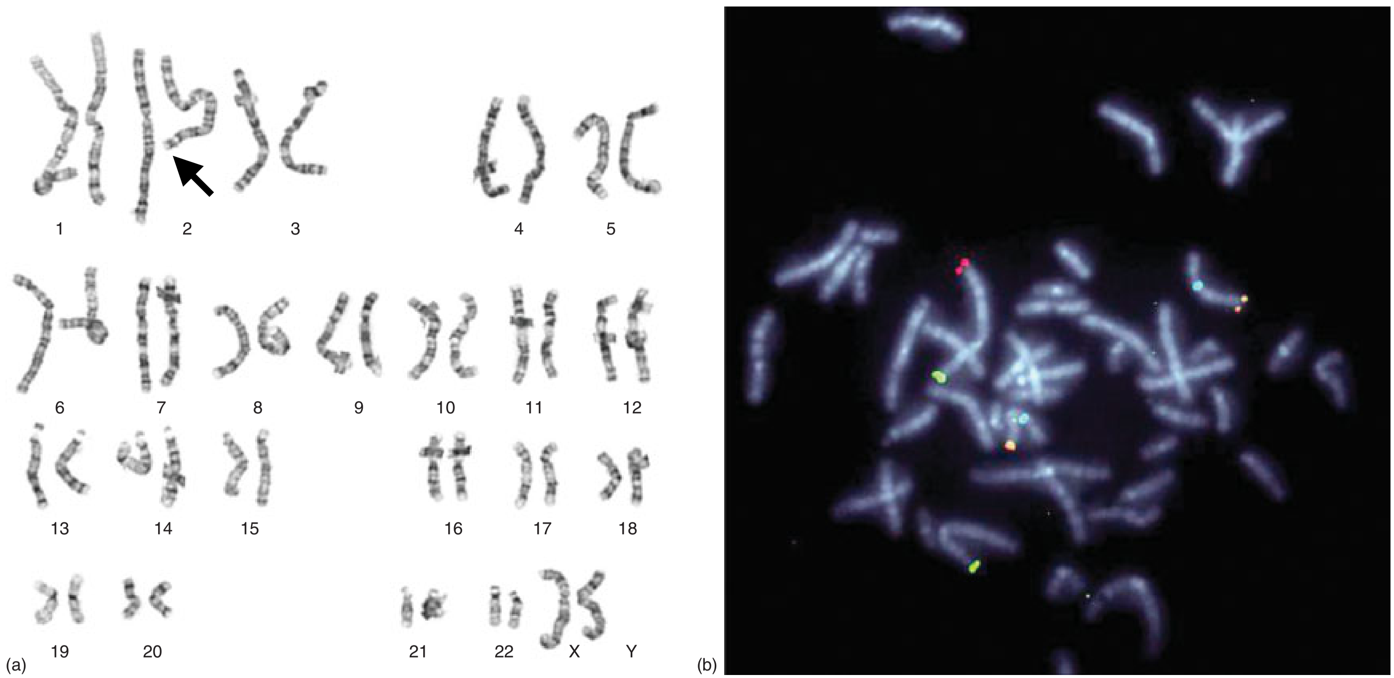

Figure 3 Karyotype (a) and partial results of a subtelomeric probe panel (ToTelVysion, Vysis, Inc., Downers Grove, IL) analysis (b) for a female patient with developmental delay and autism. The probe cocktail shown contains probes for chromosomal regions 2p (green), 2q (red), X centromere (blue) and Xq/Yq (yellow). This patient had a subtle deletion of the subtelomeric region on chromosome 2q (arrows)

et al., 1992). This technology allows results to be generated within 24 h for cases with advanced maternal age or pregnancies indicated to be at increased risk due to maternal screening results or abnormal ultrasound findings. Enumeration of signals for these five probes in uncultured amniotic fluid detects the majority (65–80%) of chromosomal abnormalities (Test and technology transfer committee of the American College of Medical Genetics, 2000). For couples at high risk for genetic disease, FISH is also valuable for assessing embryo sex and chromosome number prior to implantation [preimplantation genetic diagnosis (PGD)] so that the birth of an affected child can be avoided (Findley, 2000). As with prenatal diagnosis, the common probes used for ploidy evaluation are for chromosomes 13, 18, 21, X, and Y. For PGD of translocations when one of the parents is a known carrier, FISH with subtelomeric probes provides diagnostic information.

4. The SKY is the limit

FISHing got more interesting with the ability to simultaneously visualize all 24 human chromosome pairs with different colors (Schrock *et al*., 1996; Speicher *et al*., 1996). Spectral karyotyping (SKY, Figure 4) or Multiplex-FISH (M-FISH) techniques incorporate combinatorial or ratio-based fluorochrome labeling schemes to produce 24 colors, one for each chromosome. To accomplish this, whole chromosome probes, composed of unique and moderately repetitive sequences from an entire chromosome, are labeled with specific combinations of fluorescent dyes. The probes are generated from DNA from a particular chromosome that is isolated from the rest of the genome by flow sorting, creation of somatic cell hybrids containing a single human chromosome or area of a chromosome, or microdissection of chromosomes and subsequent amplification of the dissected DNA sequences via the PCR (Gray *et al*., 1992). Hybridization of the collection of whole chromosome probes to metaphase cells produces continuous fluorescent signals on each of the chromosomes. For SKY, the spectral characteristics of each pixel are scored by an inferometer (Schrock *et al*., 1996); whereas for M-FISH, images are collected through a series of excitation and emission filters and computer software is used to classify each chromosomal segment (Speicher *et al*., 1996). The computer then applies a distinct pseudocolor for each chromosome allowing the cytogeneticist to view a karyotype with each chromosome "painted" a different color.

This type of analysis has been especially useful for defining complex rearrangements, such as those seen in neoplastic disorders and solid tumors. For example, in a study of 30 children with acute lymphoblastic leukemia whose leukemic blast cells lacked chromosomal abnormalities detectable by conventional cytogenetics or whose blast cells had multiple chromosomal abnormalities that could not be completely characterized by G-banding analysis, SKY identified three cryptic translocations in the previously normal category and was also successful in defining the nature of the chromosomal abnormalities in 4 of the 10 patients with marker and derivative chromosomes (Matthew *et al*., 2001). SKY and M-FISH have also been used to determine the origin of de novo duplications and marker chromosomes in pre- and postnatal cases (Haddad *et al*., 1998; Uhrig *et al*., 1999).

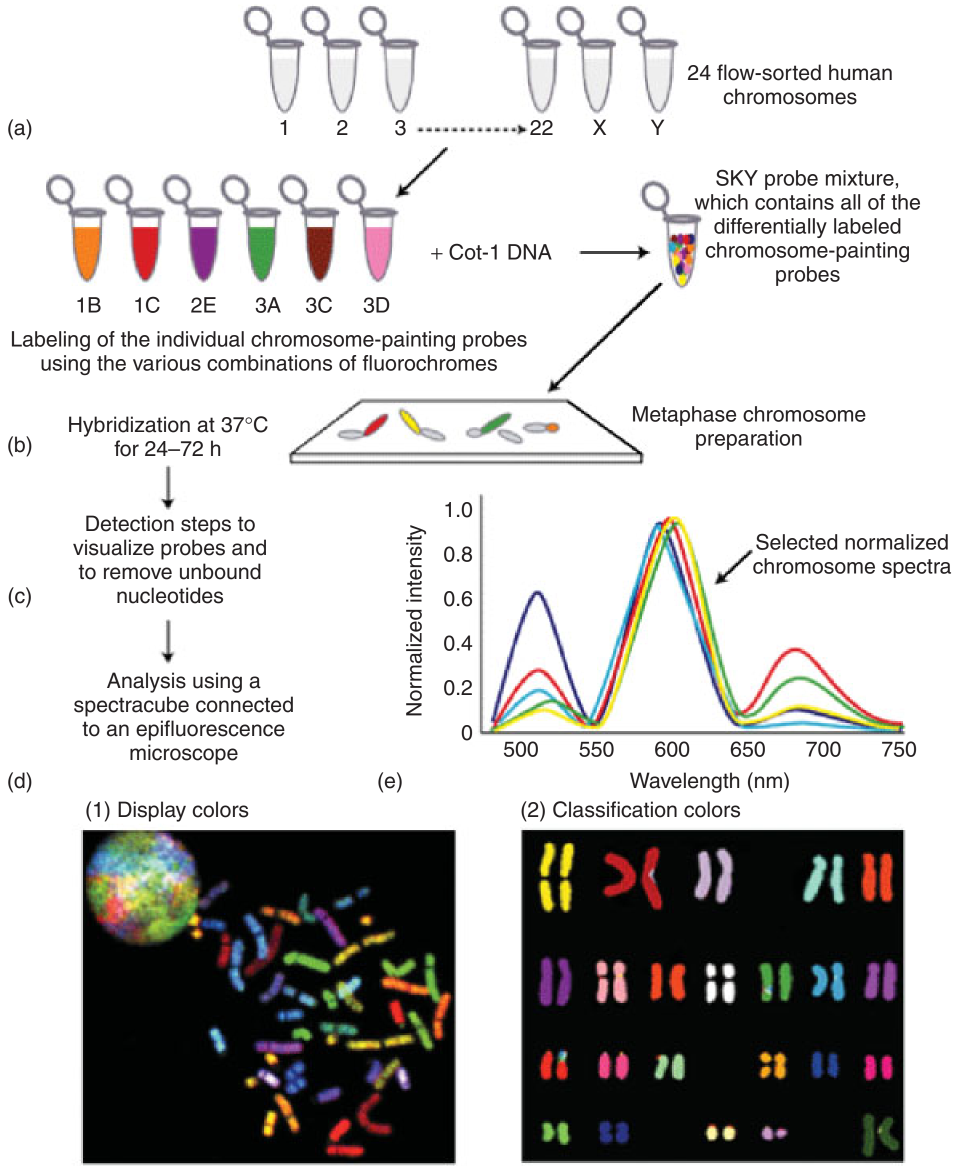

Figure 4 Schematic of cytogenetic analysis using spectral karyotyping (SKY). (a) Flow-sorted human chromosomes are combinatorially labeled with at least one, and as many as five, fluorochrome combinations to create a unique spectral color for each chromosome pair. (b) The SKY probe mixture is hybridized to a metaphase chromosome preparation. (c) Detection of the hybridized sample. (d) Visualization of the SKY hybridization using a Spectracube connected to an epifluorescence microscope. (e) Spectral classification assigns a discrete color to all pixels, which is converted to a display image that is based on the fluorescence intensities of all of the chromosome-painting probes: (1) classification colors are assigned to the chromosomes; (2) this measurement forms the basis for automated chromosome identification. (Reproduced by permission from Thomas Reed and Cambridge University Press)

Multicolor banding (Chudoba *et al*., 1999) uses similar technology to produce differential painting of specific sections of the chromosomes. Mixtures of partial-chromosome paints are labeled with various fluorochromes and a computer program analyzes metaphase chromosome data producing a pseudocolored, banded karyotype with an estimated resolution of 550-bands, regardless of chromosome length. This methodology is advantageous for the determination of breakpoints and the analysis of intrachromosomal rearrangements, and has been used to identify and classify markers and derivative chromosomes (Muller, 1997).

5. FISH and CGH chips

The introduction of comparative genomic hybridization (CGH), in which two genomes are directly compared for DNA content differences (Kallioniemi, 1992), allowed cytogenetics to identify chromosomal imbalances without directly studying the patient's chromosomes (*see* Article 23, **Comparative genomic hybridization**, Volume 1). For CGH, DNA from a test genome and DNA from a reference genome are differentially labeled in two distinct fluorochromes (red and green, respectively, for example) and are allowed to compete for hybridization sites on normal metaphase chromosomes (Figure 5). The ratio of the red to green is measured and sequences that are overrepresented or amplified in the test DNA appear more red, deleted regions appear greener, and an equal representation of test and reference appears yellow. CGH has been particularly useful for studying solid tumors and has led to the identification of several oncogenes important for ovarian cancer (Shayesteh *et al*., 1999) and pancreatic cancer (Wallrapp *et al*., 1999). CGH is limited however by its reliance on metaphase chromosomes for the detection of subtle rearrangements with an ability to distinguish chromosomal losses on the order of 5–10 Mb and amplifications of 2 Mb.

The highest resolution analysis of the genome has been promised by the recent development of CGH applied to genomic microarrays. For array CGH, vectors such as bacterial artificial chromosomes (BACs), containing cloned DNA fragments, are substituted for metaphase chromosomes as targets for the test DNA hybridization (Solinas-Toldo *et al*., 1997; Pinkel *et al*., 1998; Geschwind *et al*., 1998) (Figure 5). The genomic resolution achievable with CGH array analysis depends solely upon the map distances between markers and the length of the clones used (Solinas-Toldo *et al*., 1997). Thus, this methodology has the potential to identify chromosomal alterations on the gene level.

Most CGH array studies have been applied to malignancies, such as breast cancer (Albertson *et al*., 2000; Daigo *et al*., 2001), ovarian cancer (Schraml *et al*., 2003) and gastric cancer (Weiss *et al*., 2003). These analyses provide a high-resolution screen for detecting copy number changes of putative oncogenes and tumor suppressor genes. For constitutional studies, arrays designed to cover the entire chromosome 22 have been used to detect abnormalities that result from the gain or loss of a chromosomal region (Buckley *et al*., 2002). Focused arrays have also been developed for the detailed analysis of the subtelomeric regions (Veltman *et al*., 2002) and 1p36 (Yu *et al*., 2003). Recently, a clone set composed of >32,000 BACs with an average resolution of 75 kb has been developed

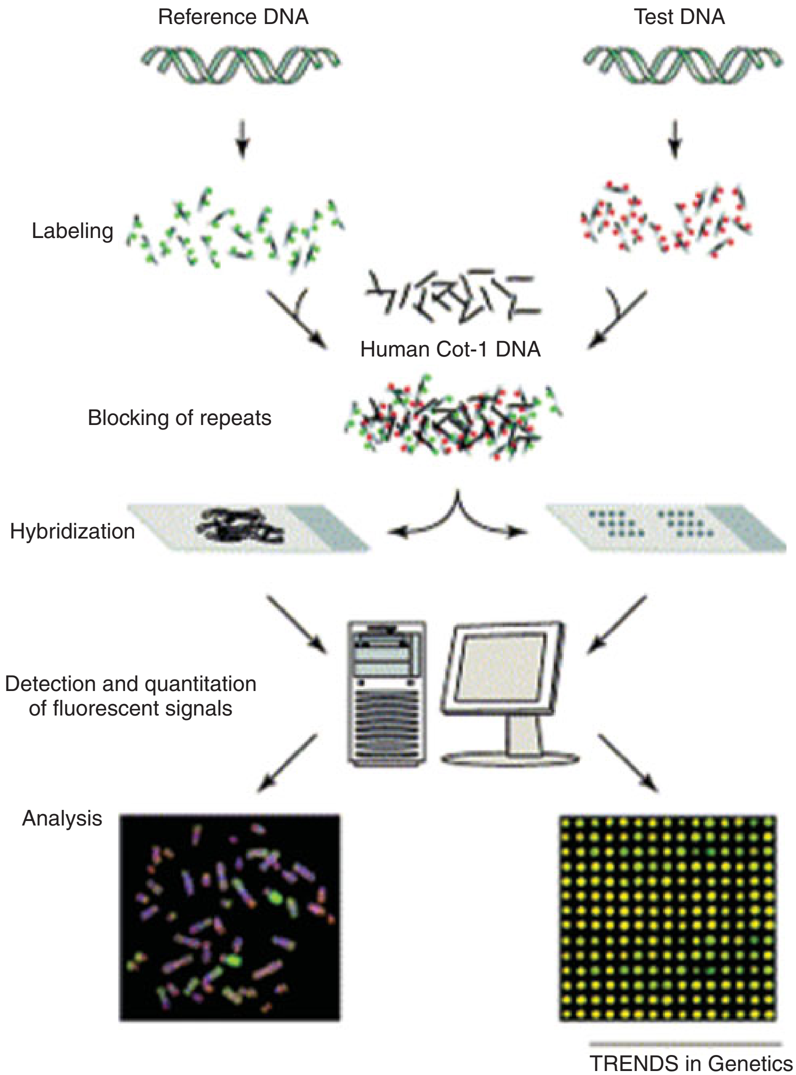

Figure 5 Comparative genomic hybridization (CGH) on metaphase spreads and arrays. Test and genomic DNAs are differentially labeled and mixed with Cot-1 DNA to block repetitive sequences. The probe hybridization mixture is placed on a slide containing metaphase chromosomes or array targets and hybridized. Fluorescent signals are detected and image-processing software identifies regions with an abnormal test: reference ratio, indicating regions with a loss or gain of DNA sequence. to cover approximately 99% of the current human genome sequence assembly (**www.bcgsc.ca/lab/mapping/bacrarray/human/**). While a wonderful research tool, the whole-genome approach of aberration detection may not be the best clinical assessment tool as it is likely to uncover many polymorphic regions with no clinical significance.

Targeted array CGH has the potential to be the major technique used for diagnosis of chromosome imbalances, due to the reduced labor compared with conventional cytogenetic analysis, its high-resolution assessment, and the promise of automation. However, array CGH will not detect balanced rearrangements such as inversions, insertions, and translocations. Thus, the original genome scanning tool, karyotypic analysis, will still be necessary for parental and family studies when an abnormality is detected with array CGH and for assessment of all cases with normal microarray results.

6. New cytogenetic horizons

While advances in cytogenetic technologies have greatly increased the ability to diagnose genetic imbalances, limitations exist. Assay sensitivities are determined by the content encompassed by the FISH probe or BAC used on an array. Thus, owing to the large size of the target sequences, small deletions and duplications within those sequences will still be overlooked. One approach to overcome this limitation is to use single copy DNA probes as short as most PCR products. ScFISH, based upon the design and synthesis of single copy DNA probes for FISH (Rogan *et al*., 2001) has detected tiny deletions in the Prader–Willi/Angelman imprinting control region and has differentiated chromosomal breakpoints for a variety of genomic rearrangements (e.g., t(9;22) in CML and the atypical deletion in Smith–Magenis syndrome) at a resolution similar to that of genomic Southern blot analysis (Knoll and Rogan, 2003). The properties of scFISH probes not only allow for detection of aberrations less than 10 kb but also reveal clinically significant heterogeneity of chromosomal breakpoints among affected individuals that have apparently identical molecular cytogenetic findings using conventional genomic FISH probes (Knoll and Rogan, 2003).

Another limitation of cytogenetic and most molecular techniques is the lack of ability to assess clinically important characteristics of the target cells. For example, routine FISH assessment of a bone marrow sample from a patient with multiple myeloma may yield normal results owing to the low percentage of diseased plasma cells. Thus, a method to enrich for or to label the cells of interest is needed to offer a sensitive and specific clinical test (Ahmann *et al*., 1998). An easy way to identify the cells is to use a specific fluorescence antibody to label the cells concurrently with the FISH probe assessment (Weber-Matthiesen *et al*., 1995).

An exciting technique with potential clinical cytogenetic application involves a liquid-based hybridization method and analysis using the Luminex flow cytometric platform. For this methodology, fluorescent tagged microspheres are coupled with single copy DNA sequences complementary to clinically relevant chromosomal regions (capture probes). To quantitate the genetic content of the specific genomic regions of interest, the oligonucleotide capture probes immobilized on the fluorescent microspheres are mixed with patient DNA samples. Hybridization of probe and target occurs in the liquid suspension and, following a wash step, the hybridized microspheres are passed through a Luminex counting device that records the fluorescence intensity of each microsphere. The fluorescence intensity
